Acknowledgement

I deeply indebted to my supervising guide and Head of the Department ***Dr. Sujatha C.H*** *Reader and Head, School of Marine Sciences, for her sustained interest and valuable guidance in my work. Without her support and scientific advices this thesis would not have been materialized.*

I am thankful to ***Prof. (Dr) Sajan. K,*** *Dean, School of Marine Sciences, for providing the necessary facilities to carry out my research.*

There are no words to express my sincere gratitude to ***Dr.Chandramohanakumar****, for his valuable and very precious worships, continuous help, his valuable advises and suggestions and facilities provided to me throughout the work. I am grateful to our teachers* ***Prof (Dr).Jacob Chacko, Prof (Dr).S.Muraleedharan Nair,*** *for their advices and timely support.*

I take this opportunity to thank ***Dr. Rosamma Stephen, Scientist F (Rtd), National Institute of Oceanography, Regional Centre, Kochi*** *for her valuable suggestions for timely completion of this thesis.*

I gratefully recall the valuable help and support of ***Dr. Ratheesh Kumar*** *and* ***Mr. Salas P.M*** *for the completion of my thesis. I express my sincere gratitude to my colleagues,* ***Ms. Manju M.N, Mrs. Resmi P, Ms. Renjitha Raveendran*** *and* ***Mr. Sanil Kumar,*** *for the timely support and cooperation. I am deeply thankful to my friend* ***Dr (Mrs). Bindu Sunil , Dr.Nisha P Aravind and Dr. Sheeba P,*** *for her valuable advises and suggestions. Samples used in the present study were collected in the King Fisher and my thanks extent to* ***Mr. Anilajan and Mr. Suresh*** *for the help they provided for the collection of samples.*

My heartfelt thanks to all especially ***Dr (Mrs). Mini Sekharan****, and all my colleagues for their timely help and support during this work.*

My sincere thanks to ***Dr. M.P. Prabhakaran, Mr. Rahul R., Mr. Shaiju P, Mr. Deepulal P M, Mr. Anoop.P.P, Mr. Gireesh Kumar T R., Mrs. Nebula Murukesh, Mrs. Dayala Joby, Mr .Baiju.P, Mr.Akhil P.S*** *and all other research scholars of this department. I sincerely thank Mr.* ***A. Arumukhadas,*** *Former Section Officer,* ***Mrs. Geetha*** *and other staff of the Department of Chemical Oceanography, for their timely service. I thank Mr.* ***P.J. Manuel,*** *Librarian, and other staff, School of Marine Sciences Library for their valuable cooperation.*

I am indebted to my parents especially to my mother, who encouraged me a lot, my husband ***Mr. Dilip Mohan*** *and my sweet daughter baby* ***Anamika*** *who always prayed for me and gave generous support.*

I thank ***Dr. M.P.Rajan, Principal,*** *N.S.S.Hindu College, Changanassery for his encouragement. I wish to pronounce my gratitude to* ***Prof. R.Prasannakumar****, Secretary, N.S.S.College's Central Committee,* ***N.S.S Management,*** *Prof.* ***Dr. Sarala Nair, Prof. Sobhanakumari, Prof (Dr). Geetha, Prof (Dr). Gopakumar, Prof (Dr). Renukadevi, Mrs. Ampily M, Dr. Sreejaya R, Smt. Sreevidya J*** *faculty members of the Department of Zoology, N.S.S.Hindu College, Changanasserry,* ***Dr.K,K Hemalatha, Dr. Balakrishnan, Dr. Sushama.S , Dr.Laksmi.R.Chandran and Dr.Umadevi*** *for their support and constant encouragement. I also wish to express my gratitude to* ***Prof. V.Sethumadhavan*** *former head of the Department of Zoology, and* ***Dr.Saraswathiamma*** *former Principal, N.S.S.College , Nemmara for their encouragement. I am very much thankful to my friend* ***Miss Praveena,K*** *Assistant Professor in Economics, N.S.S.Hindu College, Changanasserry for her*

timely and valuable help. This work would not have been completed without the support of many generous and knowledgeable people.

There are no words to express my gratitude to ***CSIR for providing Senior Research Fellowship*** *and* ***University Grants Commission*** *for providing* ***FIP*** *for the completion of my work. I thank each and every person who had directly or indirectly helped me to complete this thesis in time.*

Above all, I thank the god almighty for blessing me with the potential for the successful completion of my work.

Radhika R.

PREFACE

Estuaries are dynamic water bodies characterized by variations driven by tidal currents, meteorological factors and river discharge. Due to alterations in the physico-chemical, biological and meteorological conditions experienced in aquatic environments with respect to seasons; a detailed study of each estuarine system is a prerequisite to establish the effects of these parameters on the distribution and abundance of the fauna and flora. Cochin backwater system is facing ecological threats like environmental degradation, nutrient enrichment, habitat degradation, biodiversity loss and changes in overall functioning of the ecosystem due to urbanization and industrialization. In addition, during the past decades this ecosystem has been subjected to severe encroachment. Of late great emphasis is given to study the impact of habitat alteration in coastal areas that are beyond self-purification by the ebb and flow of tides and by seasonal flushing by the monsoonal rains. Baseline study on physical, chemical and biological alterations are lacking from Cochin backwater system, the largest estuary along the southwest coast of India. Comprehensive studies explaining the dynamics by interlinking physicochemical and biological characteristics of the estuarine systems are limited due to its complex nature. Random collections and time series studies were carried out by eminent researchers from various institutions. The present study provides a systematic approach regarding the influence of physicochemical parameters, nutrient dynamics and sedimentary parameters on different trophic levels. This type of investigation in the study region is not so far been conducted by interlinking all prominent levels of biotic and abiotic components. As all aquatic ecosystems are facing deterioration in quality and life threat, this study helps to assess the overall health of Cochin estuarine

system and can create an awareness in people the importance of conserving this natural ecosystem.

Globally more than 10 million people die every year due to either starvation or malnutrition. At this crucial time there arises the need for regular monitoring, conservation and management of fishery resources which in turn connected to phytoplankton and zooplankton potentials of the water bodies. The significance of plankton (both phytoplankton and zooplankton), in the food chain and fishery potential of the sea or any other water bodies has been realized even a century ago. Investigations on influence of the hydrobiology, nutrient dynamics and trophic level interactions would go long way in improving the quality of water resources that reflect the properties of the environment. The present work would be immensely useful for the people to implement corrective measures and would serve as a standard reference for the further studies in the Cochin estuarine system.

In the present thesis entitled" ***Implications of Hydrobiology and Nutrient dynamics on Trophic structure and Interactions in Cochin backwaters",*** an attempt has been made to assess the influence of general hydrography, nutrients and other environmental factors on the abundance, distribution and trophic interactions in Cochin backwater system. The study was based on five seasonal sampling campaigns carried out at 15 stations spread along the Cochin backwater system. The thesis is presented in the following 5 chapters. Salient features of each chapter are summarized below:

Chapter 1- General Introduction: Provides information on the topic of study, environmental factors, back ground information, the significance, review of literature, aim and scope of the present study and its objectives.

Chapter 2- Materials and Methods: This chapter deals with the description of the study area and the methodology adopted for sample collection and analysis.

Chapter 3- General Hydrograhy and Sediment Characteristics: Describes the environmental setting of the study area explaining seasonal variation in physicochemical parameters of water column and sediment characteristics. Data on hydrographical parameters, nitrogen fractionation, phosphorus fractionation and biochemical composition of the sediment samples were assessed to evaluate the trophic status.

Chapter 4- Nutrient Dynamics on Trophic Structure and Interactions: Describes primary, secondary and tertiary production in Cochin backwater system. Primary production related to cell abundance, diversity of phytoplankton that varies seasonally, concentration of various pigments and primary productivity. Secondary production refers to the seasonal abundance of zooplankton especially copepod abundance and tertiary production deals with seasonal fish landings, gut content analysis and proximate composition of dominant fish species. The spatiotemporal variation, interrelationships and trophic interactions were evaluated by statistical methods.

Chapter 5- Summary: The results and findings of the study are summarized in the fifth chapter of the thesis.

References are given at the end of each chapter. The papers published and presented are listed at the end of thesis.

Chapter 1

GENERAL INTRODUCTION

Contents

Kerala, one of the southernmost state of India, situated in between lattitude 8^{o} 15'and 12^{o} 45'N and longitude 74 ^{o} 50' and 77 ^{o} 30'E comprising an area of about 38,863 km^2 and is bestowed with coconut trees, lakes, ponds, estuaries, reservoirs, streams, rivers, backwaters, and mangroves. The eastern boundary of the state -Western Ghats is the site of origin of 44 rivers. Most of these rivers empty into the backwaters before opening into the Arabian Sea, which form the eastern boundary. It is generally accepted that estuaries or backwater systems are the most likely environment in which the first signs of life evolved and in the course of several millions of years animal life slowly adapted itself to a land living and air - breathing existence. Backwater systems of Kerala support as much biological productivity and diversity as tropical rain forests. They are responsible for the rich fishery potential of the State. Distributed along the east and west coast of India, there are a number of estuaries covering an area of approximately two million hectares, though many of them are being used for fishing and transportation very few are advantageously and scientifically managed for optimum utilization.

1.1 Significance of estuaries

Estuaries are defined as semi-enclosed bodies of water, situated at the interface between land and ocean, where seawater is measurably diluted by the inflow of freshwater (Hobbie, 2000). The term "estuary," derived from the Latin word *aestuarium*, means marsh or channel (Merriam-Webster, 1979). Based on salinity estuaries are defined as semi-enclosed coastal bodies of water that have a free connection with the open sea and within which sea water is measurably diluted with fresh water derived from land drainage (Pritchard, 1967). These are among the highly dynamic biodiverse and productive ecosystems in the world with high carrying capacity and ability to support not only a resident population but also many migratory fishes and invertebrates. They provide a direct resource for commercially important species of fishes and shellfish, but they also provide shelter and food resources for commercially important shelf species that spend some of their juvenile stages in estuarine marshes. These are also regarded as economically important ecosystems for fisheries in tropical regions (Kawabata et al., 1993) and act as transitional zone between land and sea (Bardarudeen et al., 1996).

The estuaries are always considered as biologically active zones (Kibirige and Perissinotto, 2003). Different types of trophic relationship between the phytoplankton and zooplankton have been established in estuarine systems (Perissinotto et al., 2000; Tan et al., 2004). Studies on the hydrological features of the marine and estuarine environment is of great importance since the general distribution, migration and relative abundance of marine and estuarine organisms are greatly influenced by the physico-chemical parameters.

It has been reported 61% of the world population lives along the coastal margin (Alongi, 1998) and are facing the difficulties as well as the benefits of living near the sea. The estuarine ecosystems have an outstanding direct socio economic importance for many tropical coastal regions (Aksornkoae et al., 1993; Uthoff, 1996).

1.2 Productive nature and trophic status of estuarine systems

Phytoplanktons are widely distributed in the estuarine environments. By photosynthesis these green organisms use solar radiation to transform carbon dioxide and water into carbohydrates or high energy organic compounds. The synthesis of organic material by photosynthesis is termed primary production. Since phytoplanktons are the major producers in the aquatic ecosystems, their role in the food chain is of paramount importance. Phytoplankton in the estuarine environments utilizes carbon dioxide for photosynthesis play an important role in maintaining carbon dioxide budget of the atmosphere. The larger the world's phytoplankton community, the greater is the carbon dioxide is removal from the atmosphere. Phytoplankton forms the foundation stone of world fishery. The distribution and abundance of the commercially important fish and shellfish and their larvae are dependent on some species of the phytoplankton, forming food for majority of juveniles as well as many adult fishes.

Phytoplankton is of great economic importance in the biology of the pelagic realm, particularly in estuaries and coastal waters, since it provides the primary nutritional source. They constitute the basic source of food in the sea and the initial level of food chain. These are consumed by floating and drifting animals called zooplankton which has limited powers of swimming ability. Phytoplanktons are also consumed by larger animals such as some fishes, molluscs, and crustaceans which are herbivorous that

graze upon the floating plant life. Studies related with phytoplankton provide very useful basic information for the estimation of primary production and assessment of potential resources at higher trophic levels.

Secondary production can be defined as the generation of biomass of heterotrophic (consumer) organisms in a system and is driven by the transfer of organic material between trophic levels, and represents the quantity of new cells produced through the use of assimilated food. Secondary production is sometimes defined to only include consumption of primary producers by herbivorous consumers and commonly defined to include all biomass generation by heterotrophs. The organisms responsible for secondary production include animals, zooplankton, protists, fungi and many bacteria. Thus secondary production is a composite measure of density of an animal population, biomass, and growth over time. Secondary production converts animal abundance and biomass data into a functional measure of energy flow through an ecosystem.

Different taxa are also reliable indicators of a wide spectrum of limnological conditions such as pH, nutrient concentrations and salinity. Their number was found to be reduced due to pollution. The low densities of copepods in CBW are the sign of polluted sediments or the degradation of water quality of that area. The ecological role of an organism is largely determined by its position and significance in the food web. Some important secondary producers in estuaries are mentioned below:

Copepods are ubiquitous in marine environment. Sexes are separate and can be easily distinguished by the nature of the fifth leg. Copepods are main grazers of the phytoplankton. Their oral appendages are flattened multi lobed structures carrying long plumose setae. These appendages form an efficient filtering apparatus for filtering of diatoms. Copepods form the

food of other animals, inhabiting in the surface waters especially for shoal fishes where ever copepods are abundant. One can expect a large concentration of primary and secondary carnivorous, the seasonal variations in the abundance and distribution of copepods largely determines the distribution of pelagic fishes.

These are small crustaceans commonly called water fleas. They are ubiquitous in inland aquatic habitats, but rare in the oceans. Most are 0.2-6.0 mm (0.0079-0.24mm) in long, with a down-turned head, and a carapace covering the apparently unsegmented thorax and abdomen with a single median compound eye.

The phylum Rotifera, commonly called wheel animals are microscopic and near-microscopic pseudocoelomate animals. Most rotifers are around 0.1- 0.5 mm long. Their size can range from 50μm to over 2mm and are common in freshwater environments throughout the world with a few saltwater species. Some rotifers are free swimming and truly planktonic.

Tertiary production can be defined as the production of living material per unit area (or volume) per unit time by organisms consuming the herbivores or carnivores. Losses of marine life diversity are largely the result of the conflicting usage of the coastal habitat which hence leads to degradation of habitat. The best way to conserve biodiversity is to protect habitat diversity (Tiwari et al., 2002). The fishes caught from the aquatic environment are consumed by human being thereby reducing protein deficiency. Indiscriminate exploitation of marine food source has resulted in depletion so there should be judicious and sustainable fishing and should know the quantity of the population that can be harvested. By quantifying the biomass of plankton, fish population that will be produced can be

calculated and in turn the catchable amount per year can be predicted. In order to predict, locate and exploit the marine fishery resources, hydrobiology of marine environment can play significant role (Asha and Diwakar, 2007).

Fishes are the important tertiary producers in aquatic habitats and are significant focus of the economically important and commercial fisheries. They are important source of food and recreation and are key elements in many natural and food webs. They have an impact on the physico-chemical properties of the system, in which they occur; they affect plankton, macrophytes and other aquatic organisms and they can serve as environmental indicators. Changes in the composition of a fish assemblage often indicate a variation in pH, salinity temperature regime, solutes, flow, turbidity, dissolved oxygen, substrate composition or pollution level. The gain or loss of certain species is a common consequence of the environmental change. Because fishes are conspicuous they often are the primary indicators of the toxification of streams and lakes. Because fishes are ecologically important, there is often intense commercial and recreational interest in their study. The feeding behavior of fish is as diverse as their morphology. Their actual diet at any given time depends on the availability of the food items as well as on the presence of potentially competing fish species. It is generally agreed that fishes are herbivorous, omnivorous or carnivorous, but most of them are highly adaptable in their feeding habits. Knowledge on the food and feeding habits of fishes and their trophic relationships is essential to understand how the food influences growth, abundance, migration, reproduction. The food and feeding habits of fishes from varying habitats differ in time and space and also at different stages of growth, thereby emphasizing the need for the

study of food and feeding habits of a species in more detail. The information gathered from a qualitative study of feeding habits, on the food requirements of fishes, will be useful in ecological and aquaculture studies.

1.3 Ecological aspects of Cochin backwater system

The Cochin backwater system is a positive tropical estuary which exhibits a unique ecological complex having marine, estuarine and freshwater environments at different zones. It is the largest backwater system of Kerala state, which encompasses a large number of organisms, with its problems and opportunities. It supports rich fishery resources having several species of marine fin fishes and shell fishes and acts as a sink and transformer for the agricultural and municipal wastes discharged into it. The harbor of Cochin brings a lot of economic fortune to the city of Cochin and the backwater system provides livelihood for lot of people from fishing and paddy cum prawn farming.

The discharge of fresh water from the various rivers and drainage canals cause a dynamic condition which renders the backwaters an extremely interesting and ecologically intriguing environment. The inland extensions of the Cochin backwater system with their very many water enclaves are of utmost important from the fishery point of view and are well known for their role as nursery ground for many of the commercially important species of fishes. The major hydrological variable in the Cochin backwater is salinity (Menon et al., 2000). The salinity gradient in the Cochin back water supports diverse species of flora and fauna according to their tolerance for the saline environments. The changes in the hydrology are controlled by the seasons which play an important role in regulating the migrant fauna of the estuary.

The processes regulating the biological productivity in the Cochin backwater is very complex. This estuary is influenced by heavy rain and fresh water influx during monsoon seasons ie., south west monsoon and north east monsoon. During the peak of south west monsoon, salinity gets very low values all over the regions. High tides from the Arabian Sea contribute a regular flow of salt water, which diminishes considerably towards the head of the Cochin estuary (Madhupratap, 1987). This tropical estuarine environment exhibit multitudinal features (Quasim, 2003) which characterize freshwater and seawater mixing (Menon et al., 2000) and provide breeding ground for marine organisms (Nair et al., 1988; Sarala Devi et al., 1991; Madhu et al., 2007).

Cochin backwater system has been experiencing high levels of anthropogenic pressure during the last five decades (Menon et al., 2000). Reclamation of land for harbour and urban development, intensive exploitation of resources, discharge of untreated or partially treated sewage and industrial effluents resulted in variations in the flushing characteristics and ultimately transforming the system into a eutrophic one. There are environmental problems concerning the shrinking of the estuary and loss of its biodiversity (Gopalan et al., 1980) and in the beginning of the 19th century, the total area of CBW has shrunken from 365km^2 to 256km^2 (Gopalan et al., 1983; Balachandran et al., 2005).

1.4 Review of literature

A long-term study of documenting changes in parameters like hydrography, nutrients, chlorophyll and plankton community responses are reported in Skidaway River Estuary (Verity and Borkman, 2010). Dynamics of phytoplankton, zooplankton, and nutrients in two of the largest shallow lakes in the USA (Lake Apopka, Florida) and Europe (Lago

Trasimeno, Umbria, Italy) (Havens et al., 2009). A 30-year concurrent field observation on phytoplankton, macrozoobenthos and estuarine birds in the Dutch Wadden Sea, which has been subject to decades of nutrient enrichment (Philippart et al., 2007). Studies regarding the environmental influences on the qualitative and quantitative composition of phytoplankton and zooplankton in North African coastal lagoons were also carried out (Ramdani et al., 2009). The field of phytoplankton ecology has been enriched by the outstanding contribution of Reynolds, (2006), on phycology. The effects of grazing of fishes upon zooplankton and phytoplankton communities were investigated (Williams and Moss, 2003). More precise and diversified studies on hydrography, plankton study and fisheries sector have been reported (Cabo et al., 2003; Yahia et al., 2004; Castro et al., 2005). Huang et al., (2004) examined taxonomic composition, abundance, and spatial distribution of phytoplankton in the Pearl River estuary. Phytoplankton taxonomic composition, abundance, diurnal variability and spatial distribution were examined in the Changjiang Estuary (Gao and Song, 2005). Nozais et al., (2001), reported the annual cycle of microalgal biomass in a South African temporarily open estuary. Moreover, rates or a pathway through which exogenous nutrients are converted into algal biomass is different among estuaries (Cloern, 2001). These types of uncertainties have to be addressed for the proper protection and conservation of estuarine systems. Physico-chemical parameters like nutrient concentrations, algal chlorophyll, water transparency (Carlson, 1977; Kratzer and Brezonik, 1981) and primary production measurements (Nixon, 1995) have often been employed to assess trophic status of water. Biochemical composition of organic matter in sediments has been employed as a tool to evaluate the trophic status of coastal marine systems (Dell' Anno et al., 2002; Pusceddu et al., 2003). Interactions between the

sediment and the water column play an important role in regulating phytoplankton production and the extent of bottom water hypoxia/anoxia (Kemp and Boynton, 1992). Cabo et al., (2003) studied the effect of physico-chemical factors on phytoplankton from Parana River in Argentina and suggested that the plankton occurrence and diversity would be affected directly or indirectly by water level and seasonal climatic factors. Yahia et al., (2004) studied the spatial and temporal pattern of planktonic copepods in the bay of Tunis in SW Mediterranean Sea and found that the copepods were the dominant component of mesozooplankton. Studies by Castro et al., (2005) about rotifers in three shallow lakes in Portugal and recorded peaks in diversity and abundance during summer time which was related to temperature. Kideys et al., (2005) estimated the plankton abundance, biomass and species composition of Caspian Sea and suggested that the higher value of chlorophyll was due to the decreased grazing of phytoplankton by zooplankton. Chlorophyll a and primary production in the euphotic zone of the North-West shelf of Spanish coast has been reported (Bode et al., in 1996). Planktons have been long been used as indicators of water quality (Palmer, 1969; Stoermer and Yang, 1969). Ecological study on the feeding habits of fishes has been conducted (Whitefield and Blaber, 1978). Torreele et al., (1992) investigated the development of a functional digestive system in the African Catfish *Clarius gariepinus*. Wasidewska, (1992) studied the relationship between abiotic factors and phytoplankton in Rusalka reservoir and reported that physical factors are of greater importance for the prediction of phytoplankton biomass. Virbickas, (1998) studied the regularities of changes in the production of fish population and communities in Lithuanian Rivers. Investigations on proximate composition of biochemical components of many commercially important fishes have been published (Sinha and Pal,

1990; Das and Sahu, 2001). Eutrophication due to excess supply of nutrients from industrial and domestic activities influence coastal and estuarine waters (Barmawidjaja et al., 1995; Tsujimoto et al., 2006).

Reddy et al., (2002) reported that human activities can heavily pollute a lake while studying the eutrophic status of Hussain Sagar Lake. Systematic account of diatoms in South Indian region and described both fresh and estuarine diatoms in and around Madras, with a quite explicable taxonomic description was provided by Venkataraman, (1939). Marine planktonic diatoms of Trivandrum coast have been extensively studied (Nair, 1959). Vijayalakshmi and Venugopalan, (1975) studied the diversity of phytoplankton species, pigments and succession with a note on primary production at a tidal zone in the Vellar estuary, East coast of India. Gopinathan, (1975b), described some new distributional records of plankton diatoms from the Indian Seas. Thresiamma and Nair, (1980) investigated the qualitative and quantitative analysis of planktonic diatoms of Vizhinjam, the southwest coast of India. Primary productivity of the exclusive economic zone of India and the factors governing phytoplankton production was investigated (Nair and Gopinathan, 1981). Sewel, (1924, 1934) has studied plankton, more especially the copepods of the Chilka Lake and the salt lakes of Calcutta. A preliminary study of the plankton of the Chilka Lake was done by Devasundaram and Roy, (1954). Jhingran, (1977) reported that all major estuarine systems are rich in fishery potential. Biological productivity and fishery potential in the coastal waters off Bombay was investigated by Varshney et al., (1982). A comparative study on zooplankton in polluted and unpolluted waters of Gujarat was made by Desai et al., (1983). The secondary production of Indian Ocean can be calculated from zooplankton biomass values (Dalal, 1986). Santra et

al., 1989, studied the seasonal fluctuations of phytoplankton in Bhagirathi-Hoogly estuary, in West Bengal. Khanna et al., (1993) studied the phytoplankton ecology of the River Ganga and reported a negative correlation of water temperature with phytoplankton and zooplankton production. The values of biological factors increases with increase in temperature have got direct effect on the biology of Sagar Lake (Agarwal et al., (1995). Waste waters from industries with high temperature lead marked ill effect on water quality, planktons, and fish fauna of the Lake (Pandey, 1995). Relation between the phytoplankton and zooplankton was established (Singh 1990; Bucka et al., 1993; Baruah et al., 1997; Khan et al 1998). Vareethiah and Haneefa, (1998) reported that phytoplankton biomass is known to control fishery potential of estuaries to a greater extent. Primary productivity and chlorophyll a of the inshore area at Tuticorin was recorded by Gopinathan et al., (1994). The chemical state of many nutrients in the water bodies are controlled by the hydrogen ion concentration (Horne and Goldman, 1994 ; Habib et al., 1997) reported that light have direct influence on phytoplankton growth and temperature acts as the limiting factor for algal development. Elskens et al., (1997) studied the contribution of nitrate to the uptake of nitrogen by phytoplankton in the ocean and reported that nitrate into the euphotic zone appears to be a major controlling factor regulating the standing stock and production of phytoplankton. From the studies about the plankton community Sanganer by Chaturvedi et al., (1999) revealed that some planktons like *Chlorella* and *Closterium* grew well in polluted waters and acts as indicators of organic pollution (Borse et al., 2003; Webber et al., 2005). Sharma (2000a, b) suggested that rotifers depict a qualitative predominance in floodplain lakes. Seasonal periodicity of plankton in Ganga river has been assessed (Khanna et al., 2000; Sath et al., 2000). Godhantaraman, (2001) reported

the abundance of plankton exhibited a clear seasonal variation and showed highest in summer and lowest in Monsoon. Bhava and Borse, (2001) reported an inverse relationship between salinity and plankton production. Gowda et al., (2001) recorded the abundance and distribution of phytoplankton in the Nethravathy estuary. Malu, (2001) reported the phytoplankton diversity on Lonar Lake. The distribution and abundance of phytoplankton from Adayar estuary has been investigated (Eswari and Ramanibai, 2002). Yalavarthy Eswari, (2002) studied the hydrobiology of red hills reservoir in North Chennai reported that phosphate act as a limiting factor for the growth of plankton. Das, (2002) studied the diversity and zooplankton population with increase in salinity. Salaskar and Yeragi, (2003) studied the seasonal fluctuation of plankton population in Powai Lake in Mumbai and reached a direct relation between dissolved oxygen and phytoplankton. Sheeba and Ramanujan, (2003) identified 38 genera of phytoplankton together with physicochemical parameters of water at monthly intervals in the estuarine environment of Ithikkara River, southern Kerala. Sharma, (2005) reported that water temperature directly influence the abundance of rotifers in the flood plain lakes of Brahmaputra basin. Roy et al., (2006) investigated the spatial variation of phytoplankton pigments along the south west coast of India. Madhu et al., (2006) investigated the distribution of phytoplankton in western Bay of Bengal during summer, winter and spring inter monsoon period and found that there is a lack of pronounced seasonal variation in the phytoplankton standing stock (chlorophyll a) and primary production.

Survey of rotifer fauna was conducted in twenty reservoirs of major river systems in peninsular India during 1995-96 have been carried out (Sukumaran and Das, 2004). Many researchers have studied the

distribution, population density and biomass of the zooplankton and about the hydrography of Arabian Sea and Bay of Bengal (Jyothibabu et al., 2006; Madhu et al., 2007).

Investigations on the feeding habits of some fishes of Calicut and madras coasts were made by Venkataraman, (1960) those of Gulf of Mannar and Palk Bay by Talwar, (1962) and those of Bombay coast by Suseelan and Somasekharan, (1967). Studies were done in the food and feeding habits of some teleosts like *Psettodus erumei* (Mathew and Balakrishnan, 1976). Interspecific and intraspecific competition for food in fishes cohabiting the same location was studied by Thomas (1962), Mc Comish, (1966), Clifford, (1968). Keast and Deirdrewebb, (1966) studied mouth and body form relative to feeding ecology of fishes. Various researchers have studied the diversity of fishes in India. Ajith Kumar and Vijayan, (1987) studied the fish fauna of Keoladeo National Park, Bharatpur. Reviews of the literature on the methods of gut content analysis have been made by several workers Hynes, 1950; Pillay, 1952; Rounsefell and Everhart, 1953; Hyslop, 1980). Whole body and elemental and proximate composition of Atlantic salmon was done by Shearer et.al (1994) during its life cycle. Raju Thomas et al., (2002) have given a detailed list of freshwater fish fauna of Kerala. The studies on prevailing quality of environment form the basis for understanding impacts of a particular anthropogenic stress (Kulkarni et al., 2011).

Reports on aquatic pollution with special reference to Kuttanad region of Vembanad Lake revealed that this particular region has become a dumping yard for agricultural wastes (Padmakumar, 1987). While studying the water quality of retting zones of Vembanad lake, Bijoy Nandan et al., (1989) reported that salinity plays an important role in the distribution of

zooplankton. The effect of salinity intrusion has significant influence on the ecology of water bodies (Nair et al., 1995). Phosphorus fractionation was employed to find the bioavailability of phosphorus and its seasonal variations in the Panangad region of Cochin estuary (Renjith et al., 2011). Redox status of the Cochin estuarine system was established by using rare earths elements in sediments (Deepulal et al., 2012).

Variability in nature and composition of organic matter in the surficial sediments of mangrove and estuarine systems of Cochin were investigated (Joseph et al., 2008). The phosphorus fractions in three tropical mangrove systems of Cochin region were analysed by sequential extraction method (Joseph et al., 2011). Texture, total organic carbon, total nitrogen and stable isotopic ratios of carbon ($\delta^{13}C$) and nitrogen ($\delta\ ^{15}N$) in surface sediments of Cochin estuary was analysed to identify major sources of organic matter (Gireeshkumar et al., 2012). Different forms of sedimentary phosphorous in the Cochin estuary and their spatial and seasonal variability, bioavailability, and the changes in the P biogeochemistry along the salinity gradient of the estuary have been assessed (Gireeshkumar et al., 2013). A close coupling between enriched levels of nutrients and the absence of *Trichodesmium* in the Cochin backwaters was established by historic and fresh time series data evidences (Martin et al., 2012).

Biological characteristics of Cochin estuary were investigated by many researchers including Kurian et al., (1975); Unnithan et al., (1977), Saraladevi, (1989) and Joy et al., (1990). Sankaranarayanan and Qasim, (1969) studied the nutrients of the Cochin estuary in relation to environmental characteristics. Zooplankton distribution along the salinity gradient in the Cochin backwaters before and after monsoon was first studied by Nair and Tranton, (1971). Gopinathan (1972), studied the qualitative and

quantitative analysis on phytoplankton of the Cochin estuary and described 120 species. Devassy and Bhattathiri, (1974) analyzed the phytoplankton ecology in the Cochin estuary. Primary production in the Vembanad Lake was assessed by Nair et al., 1975. Joseph and Nair, (1975). The general hydrography of the Cochin estuary has been investigated by several investigators (Qasim and Gopinathan, 1969; Anirudhan et al., 1987; Pylee et al., 1990). In 1975, Joseph and Pillai studied the seasonal and spatial distribution of phytoplankton in Cochin backwaters. Pillai et al., 1975 studied the plankton production in relation to the environmental parameters in Vembanad Lake. Seasonal fluctuations in the abundance of phytoplankton in the Cochin backwaters were studied by Kumaran and Rao, (1975). Gopinathan (1975a) described an account of the estuarine diatoms present in various estuarine systems in India, their occurrence, seasonal fluctuations and distribution in the various estuaries particularly from Cochin backwater. Knowledge on the various aspects of the physico chemical parameters of this estuary is essential for assessing the water quality and various biogeochemical processes and also improving future guidelines on the estuarine management (Beenamma Jacob, 1993). The role of diatoms as pollution indicators has already been reported (Venkateswarulu et al., 1994). Growth constants, mean generation time and chlorophyll in relation to cell numbers and ^{14}C uptake in few unialgal cultures of selected phytoplankters isolated from Cochin estuary have been estimated (Madhu et al, 2007). Thorough study of morphology, biology and development of *Liza macrolepis* and *Mugil cunnensius* observed that early stages of both the species feed on phyto and zooplankton while the adults are mainly bottom feeders (Sunny, 1976). Species composition and distribution patterns of copepods did not change much over recurring observations which shows that the species are highly adapted to their niches (Haridas et al., 1980). Chemical condition and

physical changes are responsible for the temporal distribution of zooplankton (Madhupratap, 1987).

Large scale fish mortality has been observed on several occasions (Azis and Nair, 1981). Kurup, (1982) presented a complete systematic list of the fishes of the Vembanad Lake and their frequency of occurrence. The seasonal distribution of phytoplankton in Cochin backwaters has been reported (Jayalakshmi et al., 1986). Selvaraj and Kumaraguru (1997) noticed that higher dissolved oxygen concentration was favourable to the growth of *Microcystis aeruginosa*. A detailed review on physicochemical as well as biological aspects of CBW has been published (Menon et al., 2000).

Attempt was made to evaluate the photosynthetic pigments at the dredged and non-dredged sites in the Cochin harbour (Rasheed et al., 2000). Seasonal variation of phytoplankton abundance and productivity were studied in the surf zone of the Cochin backwaters based on cell counts, Chlorophyll a, photosynthesis and hydrographic parameters Selvaraj et al., (2003). Alkershi et al., (2003), studied the contribution of size fractions of planktonic algae to the primary organic productivity in the coastal waters off Cochin. Renjith et al., (2004) studied the primary production at selected stations in Cochin estuary and established a trimodal annual variation with peaks during April, July and November, maximum production being in November and minimum in June.

Investigations were carried out on food of some demersal fishes from the trawl grounds of Cochin (George et al., 1968). Knowledge of the food and feeding habits is important in fundamental community analysis for studies of food webs, trophodynamics resource partitioning and ecological energetic (Landenberger, 1968). A qualitative study of feeding habits together information on the food requirements of fishes will be

useful in ecological and aquaculture studies (Ramanathan et al., 1975). It is well established that the quantitative and qualitative composition of the food of a species is essential to understand many aspects concerning the fish (Gopinathan Menon and Muthaih, 1987). Extensive works were carried out on the qualitative and quantitative aspects of phytoplankton, pigments and primary productivity in the South west coast of India, mostly confined to the Cochin estuary (Gopinathan et al., 1974; Joseph and Pillai, 1975; Thangaraj 1984; Jayalakshmi et al., 1986, Selveraj, 2000, 2003; Jyothibabu et al., 2006, Madhu et al., 2007; Sanilkumar, 2009, Aneeshkumar 2009). Eutrophication and related anoxia was reported by Martin et al., (2012). Significant spatial and temporal variability of physico-chemical characteristics and productivity patterns are among the important characteristics of estuaries (Renjith et al., 2012). Pigment characterization and sedimentary biomarker pigments around Cochin estuary situated in the southwest coast of India were determined by HPLC method (Aneeshkumar, 2009). Fucoxanthin, an indicator of diatoms (Bacillariophyceae) was observed to be the most abundant carotenoid pigment in the estuary (Aneeshkumar and Sujatha, 2012)

1.5 Aim and scope of the present study

As a result of massive reclamation for the rapid urbanization and industrialization, the Cochin backwaters are facing severe ecological problems including eutrophication (Gopalan et al., 1983, Martin et al., 2012). Sixteen major and several minor industries are located on the banks of River Periyar discharge untreated or partially treated wastes containing large quantities of nutrient elements like nitrogen, phosphorous and trace metals into the estuary (Balachandran et al., 2003). Likewise, the domestic waste from the Cochin metropolitan city also creates organic pollution. All

these activities eventually lead to the changes in the population and structure of trophic webs and even affected the overall functioning of this ecosystem (Unnithan et al., 1975; Menon et al., 2000).

Several studies have been conducted in the Cochin backwaters on various physico-chemical (Sankaranarayanan and Qasim, 1969; Shyanamma and Balakrishnan, 1973) and biological characteristics (Madhupratap et al., 1975; Qasim, 2003). Environmental studies in the Cochin backwaters, revealed that seasonal fluctuations in salinity created by the monsoonal rainfall and associated run off is a major factor controlling the distribution and abundance of micro- and mesozooplankton (Madhu et al., 2007). Combined effects of hydrographic parameters and other biological features induce variations in diversity of the fauna and flora in the estuary.

In the past decades many studies have been undertaken by different researchers regarding phytoplankton composition and structure of zooplankton and fishes in different dimensions. Eventhough Cochin estuary has been subjected to intense biological study, the information available on the varying aspects of hydrography and biology has not fully described the changing biological environment. The anthropogenic stress has imposed changes in physical, chemical and biological characteristics and habitat alterations in this unique ecosystem , which demand a new approach for the quality assessment of the system, linking environmental and biological parameters.

Despite the numerous specific works that have been carried out in the Cochin estuary on physicochemical and biological characteristics, a comprehensive study covering the combined effects of hydrobiology and nutrient dynamics on trophic structure has not been attempted. An

integrated approach relating biological as wells physicochemical aspects with respect to seasons are not available for this unique backwater ecosystem. The information on the trophic structure and dynamics of Cochin backwater system would form a useful tool for further ecological assessment and will be applicable to monitor any similar tropical ecosystem. In this context, the present investigation, intends to evaluate the implications of the hydrobiology and nutrient dynamics on the trophic relationship and community structure in the Cochin backwaters.

The objectives of the present study:

- To analyze the seasonal variation in general hydrography, sediment characteristics including enrichment of nutrients from land runoff, nitrogen fractionation, phosphorous fractionation and biochemical composition of sediments in the Cochin backwater system
- To assess the spatial and seasonal variation of phytoplankton community blooming and correlation of fertility with biomass
- To study the seasonal distribution of zooplankton
- To study the trophic relationship between primary, secondary and tertiary consumers and to trace ecological indicators if any
- To assess the seasonal fish landings from the respective landing centres adjacent to sampling sites and to evaluate the damage to estuarine fishes
- To analyse and study the gut content analysis of selected fishes
- To analyse and evaluate the complexities of coastal ecosystems and the impact of hydrology on ecosystem services.

Chapter 2

MATERIALS AND METHODS

Contents

2.1 Description of the study area

Vembanad Kol Wetland was included in the list of wetlands of international importance, as defined by the Ramsar Convention for the conservation and sustainable utilization of wetlands. It is a home to more than 20,000 waterfowls and serves as an ideal habitat for shrimps. Major livelihood activities of the people living on the shores of the lake include: agriculture, fishing, tourism, inland navigation, coir retting and lime shell collection. Uncontrolled mining of shells from the lakebed is also posing a threat to the ecosystem. Vembanad Lake extends from Alappuzha in the south to Azheekode in the north. This wetland system covers an area of over 2033.02 km². The lake is fed by 10 rivers flowing into it including the six major rivers of central Kerala namely: Achenkovil, Manimala,

Meenachil, Muvattupuzha, Pamba and Periyar. There are three islands located in the lake viz., Pathiramanal, Perumbalam and Pallippuram. River Periyar evacuates into the Cochin backwater system in the north and Muvattupuzha River in the central part.

Cochin backwater system situated at the tip of the northern Vembanad lake is regarded as a positive tropical estuary located between 9^{o} 14' to 10^{o} 12'N and $76^{o}10$ to 76^{o} 36'E with its northern boundary at Azheekode and southern boundary at Thannermukkom bund. The estuary has a length of 80 km and width varies from 500 to 4000m. It has been regarded as the second largest estuarine system in India, fed by six rivers with fresh water discharge of about 291,010 m^3 per year (Srinivas et al., 2003). It is permanently connected to Arabian Sea by 450 m wide channel at the bar mouth. There are three seasonal conditions prevailing in the estuary viz., pre monsoon (PRE), monsoon (MON) and post monsoon (POM). During premonsoon season (February-May), warm climate prevails over the coast, runoff is least and the estuary is predominantly marine in nature. The environment is more or less stable, well mixed and homogenous water mass is present. This estuary is under the profound influence of monsoon (June - September). It has been reported that about 71% of annual rainfall is contributed by monsoon (Jayaprakash, 2002). Hydrobiological studies (Menon et al., 2000) revealed that the high flushing during monsoon completely transforms the estuary into a freshwater habitat. Postmonsoon (October-January) is generally the stabilization period and is characterized by diminished river discharge and tides gradually gain momentum as the estuarine condition change to partially mixed type.

The rapid industrialization and the increase in population around the Cochin estuary have resulted in the discharge of a heavy load of the inorganic and organic wastes. The pollutants of greatest concern in the estuarine ecosystem are those which are persistent, such as toxic heavy metals, insecticides and pesticides. Organic materials such as domestic sewage and food processing wastes are rapidly decomposed and often enrich the elements essential for plant nutrition and productivity. Pollutants from industrial units like the Fertilizers and Chemicals Travancore Limited (FACT), Indian Rare Earths (IRE), Hindusthan News Print Factory, Hindusthan Organic Chemicals (HOCL), BPCL-Kochi refinery and Cochin Port area (handling large quantities of sulphur, crude oil and other petroleum products) find their way to this backwater system. Domestic sewage channels, coconut husk retting yards also contribute huge loads of organic matter and nutrients into the water body every year (Stephen, 1985).

2.2 Sampling and analytical methodology

Seasonal samplings of water, sediments and fish landings were carried out from the fifteen selected stations (S1 to S15) (figure 2.1) spread across Cochin backwater system. The samples were collected in five sampling campaigns that were scheduled during January 2009, April 2009, August 2009, January 2010 and April 2010, representing three seasons (premonsoon, monsoon and postmonsoon). Water samples (both surface and bottom layers) were collected using Niskin Sampler and surface sediment samples were taken using Van Veen Grab. Water samples for general hydrography and nutrient analysis was subsampled into high density polyethylene bottles, kept on ice bags transported to laboratory and analysed without delay.

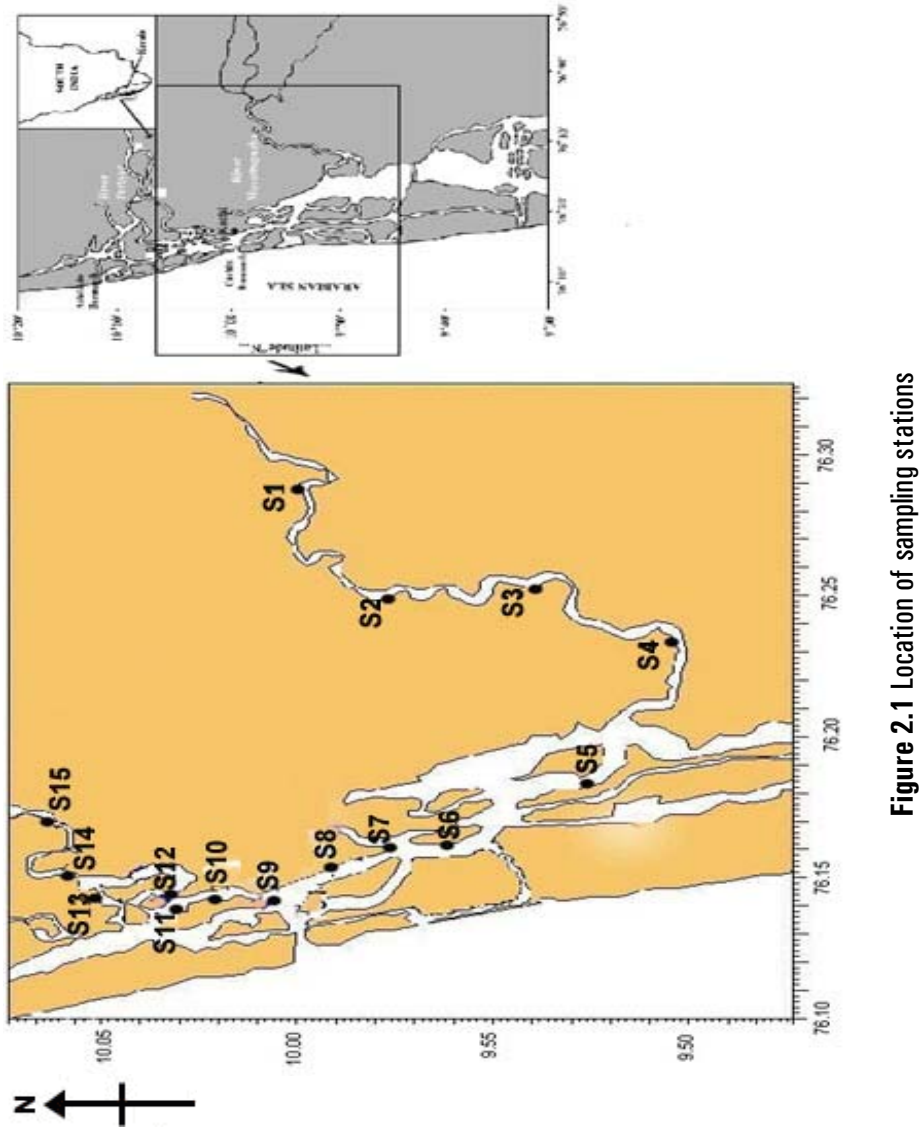

Figure 2.1 Location of sampling stations

Table 2.1 General features of sampling stations

Station Code	Place	Average Depth (m)	Latitude	Longitude	Description
S1	Karippadam	4.3	9⁰47.646'N	076⁰ 25.708'E	Thickly populated area with outflow of domestic wastes

2.2.1 General hydrographic parameters

Hydrographic parameters such as pH, dissolved oxygen, carbon dioxide, temperature, salinity, alkalinity, hardness, rainfall, depth and transparency were determined. Nutrients like nitrite-N, nitrate-N, ammonia-N, phosphate, silicate, iron were also estimated in the water samples.

Rainfall data were obtained from the meteorological Centre, Trivandrum (Govt. of India). Tide data was collected from Cochin Port Trust (Govt. of India). Measurement of transparency of water column was carried out with Secchi disc and extinction coefficient was calculated using the formula (Michael, 1984).

Extinction Coefficient= 1.7/depth in meters

pH measurements of water samples were made using a portable pH meter (Perkin Elmer, accuracy, ± 0. 01). Temperature was measured using a precision mercury thermometer graduated from 0-50^{o} C with accuracy of ±0.01^{o}C. Immediately after collecting the water sample in a narrow mouthed polyethylene bottle, the thermometer was introduced into the water column upto 5 cm. Salinity was estimated by Mohr- Knudsen method (Muller, 1999). Modified Winkler method was used for the estimation of dissolved oxygen (Hansen, 1999). Free CO_2 was determined with NaOH reagent and phenolphthalein indicator (Golterman et al., 1978). Alkalinity of the water samples were estimated by the method of Koroleff (Anderson et al., 1999). Five day biochemical oxygen demand test (BOD_5) employed for determination of BOD values of water samples (APHA, 1995). The dissolved oxygen in sample was determined before and after 5 days of incubation.

2.2.2 Estimation of nutrients in water column.

Nutrients (nitrite, nitrate, phosphate and silicate) were estimated spectophotometrically using standard methods.

Nitrite

NO_2^- was estimated using the standard procedure suggested by Grasshoff et al., (1999) in which the nitrite formed an azodye with

sulphanilamide and N-1 naphthyl ethylene diamine dihydrochloride. The spectrophotometric determination was done using UV-Vis spectrophotometer (Genesys 10 UV- Thermospectronic).

Nitrate

NO_3^- was reduced to NO_2^- using copper coated cadmium granules and determined as nitrite as outlined above (Grasshoff et al., 1999).

Dissolved inorganic phosphate

All methods for the determination of dissolved inorganic phosphate in water samples is based on the reaction of the ions with an acidified molybdate reagent to yield a phosphomolybdate heteropoly acid, which is then reduced to a intense blue coloured compound (Grasshoff et al., 1999). A known volume of sample was treated with mixed reagent and acidified ascorbic acid and the absorbance of the resulting blue complex was measured at 880nm using spectrophotometer.

Silicate

The determination of dissolved silicon compounds in natural waters is based on the formation of a yellow silicomolybdic acid when an acid sample is treated with a molybdate solution. This complex was reduced with ascorbic acid and absorbance was measured at 880nm (Grasshoff et al., 1999).

Iron

Water samples were preconcentrated according to Grasshoff et al., (1999); concentration of iron was estimated by Atomic absorption spectrometer (Perkin Elmer 3110).

2.2.3 General sediment characteristics

Each sample were transferred to polythene bottles using a plastic spatula and made airtight and taken to the laboratory for the further analysis under ice-cold storage conditions. Approximately, 200 g of sediment from each sample was dried in Freeze drier equipment (Beetta instruments and equipments, Chennai). Dried sediments were homogenized using a mortar and pestle, sieved through a 230 mesh sieve and used for the analysis of total organic carbon, CHNS analysis, nutrients and biochemical composition.

pH of the fresh wet sediments was measured in situ using a potable pH meter calibrated with buffer solutions. Redox potential of the fresh wet sediment was measured in situ using a portable E^h meter employing Zobell's solution for the calibration of the electrodes (Brassard, 1997).

Texture analysis of sediments

The textural characteristics of the sediments were determined by pipette analysis (Folk 1980), after removing the inorganic carbonates using 10% HCl and organic matter using H_2O_2. Sediment was wet sieved through a 63-μm sieve to collect the sand fraction. The mud fraction was divided into silt (63-4 μm) and clay (<4 μm) fractions by timed gravimetric extraction of the dispersed sediments.

Total Organic Carbon

Total organic carbon (TOC) was also determined using a CHN analyzer after removing the inorganic carbon with 1 N HCl (Tung and Tanner, 2003).

Total Organic Matter (TOM)

TOM was obtained by multiplying the Total organic carbon values with 1.724 (Nelson et al., 1996).

2.2.4 Fractionation of nitrogen in sediments

The analyses of nitrite, nitrate and ammonia were carried out by the "KCl equilibrium extraction method" (Agemian, 1997) which involves shaking of the sediment sample with a solution of KCl (2N) at room temperature for a period of one hour followed by filtration using standard filtration equipment and Whatman 42 filter paper. The filtrate containing nitrogen in the dissolved state was stored at 4^{o}C until analysis. From the filtrate the nitrite, nitrate, ammonia and were quantitatively estimated by spectrophotometric analyses as described earlier. Total nitrogen in sediments was determined by the following procedure. Sediment samples were digested in sulphuric acid in the presence of potassium sulphate and copper sulphate catalyst (Agemian, 1997). Organic compounds of nitrogen as well as free inorganic forms were thus converted to ammonium ions which were determined spectrophotometrically using indophenol blue method. Total nitrogen was estimated by CHNS analyser (Vario EL III CHNS Analyzer.).

2.2.5 Fractionation of phosphorous in sediments

The sequential extraction scheme by Golterman, (1996) using chelating agents was employed for estimating different phosphorus fractions (figure 2.2). Compared with the other methods, chelating agents allow a specific extraction of inorganic phosphorus with less destruction of organic phosphorus (Golterman, 1996). Iron bound phosphorus (Fe-IP) was extracted with buffered Ca-EDTA/dithionite and calcium bound fraction (Ca-IP) subsequently with Na-EDTA. In the next step, acid soluble organic phosphorus (ASOP) was extracted with H_2SO_4 and then alkali soluble organic

phosphorus (Alk-OP) with 2M NaOH at 90°C for 2 hours. Residual organic phosphorous (ROP) was measured after 1 hour $K_2S_2O_8$ digestion in acid medium. All the extractions were carried out under mild continuous shaking and the results are expressed on the dry weight basis. Generally, iron and calcium bound inorganic fractions and acid soluble organic fractions of phosphorous are considered to be bioavailable (Diaz-Espejo et al., 1999).

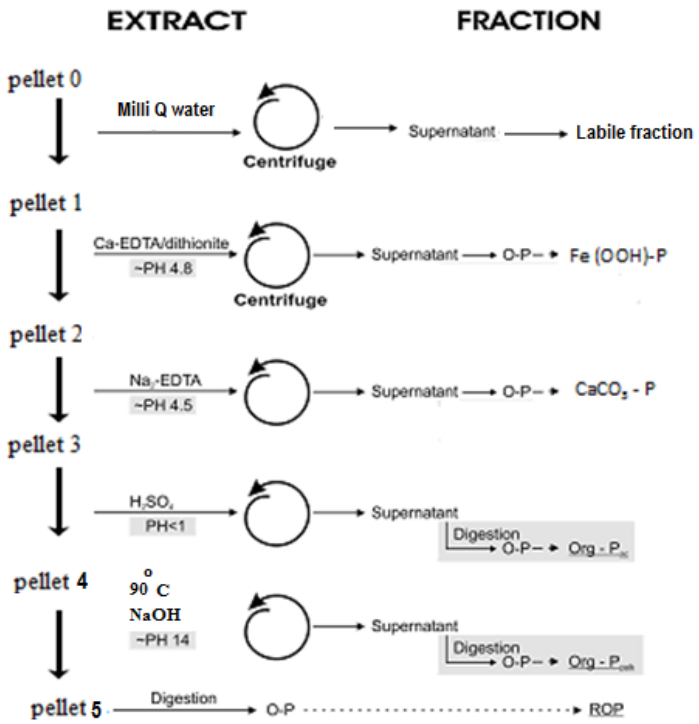

Figure 2.2 Sequential extraction scheme for phosphorus fractionation

2.2.6 Biochemical composition of sediments

Spectrophotometric methods were employed for the determination of biochemical compounds in sediments. Proteins (PRT) analyses were carried out following the procedure of Lowry et al., (1951), as modified by Rice, (1982) to account for the reactivity of phenolic compounds, with albumin as the standard. The amount of protein nitrogen was obtained by

multiplying protein with a factor of 0.16 (Mayer et al., 1986). Total carbohydrates (CHO) were analyzed according to Dubois et al., (1956), using glucose as the standard. Total lipids (LPD) were extracted according to Bligh and Dyer (1959), and estimated according to Barnes and Blackstock, (1973) using Cholesterol as the standard. All the analyses were carried out in triplicates and the average value was reported. The sum of all PRT, CHO and LPD was defined as the labile or easily assimilable organic fraction (Danovaro et al., 1993; Cividanes et al., 2002). Tannin and lignin in sediments were extracted using 0.05M NaOH at 60^{o} for 90 minutes and the estimated spectrophotometrically by the sodium tungstate-phosphomolybdic acid method (Nair et al., 1989; APHA, 1995), using tannic acid as the standard. The principle involved is the development of a blue colour on reduction of Folin phenol reagent by the aromatic hydroxyl groups present in tannins and lignins. The effects of Mg and Ca hydroxides and/or bicarbonates present in the seawater were suppressed by the addition of trisodium citrate solution (Nair et al., 1989). Chlorophyll pigments in sediments were determined spectrophotometrically after extracting with 90 % acetone according to (Lorenzen, 1967; APHA, 1995)

2.2.7 Primary Production

Plankton sampling and Enumeration

The procedure adopted in the present study was phytoplankton count based on Phytoplankton Identification Manual [Fritsch, (1935); Prescott, (1969); Santhanam et et al., (1975); Verlencar and Somshekar Desai, (2004); Mitra et al., (2006); Dona et al., (2004)]. Photographs of the identified phytoplanktons in the study area are shown in figure 2.3. Phytoplankton production and distribution were examined over a period of 15 months for phytoplankton ecology from 15 sampling stations. In order

to prevent the decay of the samples the fixation and preservation was carried out. The preserved samples are immediately stored in the high quality polyethylene bottles and neatly labeled. The labeling specifies the date, time, location of the station and type of gear used. Record was kept for cells in good or vigorous condition and those in the poor condition. Water samples were collected using Niskin sampler and 50L of water was filtered through phytoplankton net of 20µm mesh size made of bolting silk. The filtrate was preserved in 4% neutralized formaldehyde/Lugol's iodine solution. The buffered formalin was prepared by adding 30gm Borax b (Sodium tetraborate) into 1L formalin. The pH of the preserving medium was maintained at about 8.2. The preservation was done onboard immediately after collection. Quantitative analysis was done employing Sedgewick-Rafter cell. A settling and siphoning procedure was followed to concentrate samples from 250 ml to 10 ml (Utermohl, 1958). Species identification was done using a Nikon E200 light microscope. For counting phytoplankton cells and identification of genera and species, two 1ml replicates of concentrated samples were transferred into Sedge-wick-rafter cell and examined microscopically at 200x magnification; the whole slide (1000 fields) was counted for diatoms, dinoflagellates and silicoflagellates. For analyzing phytoplankton cell counts and composition, water samples from each depth were fixed in Lugol's iodine (1% w/v) and 3% formaldehyde and stored in dark until taken up for analyses. The number of phytoplankton present in all the grids was calculated. The total number of plankton present in 1 L of water sample was calculated using the formula.

$$N = (n*v*1000)/V$$

Where, N = number of phytoplankton per Litre of water filtered

n = average number of phytoplankton in 1ml of plankton sample

v = volume of plankton concentrate in 1ml

V = total volume of water filtered in Litre

Phytoplankton pigments

Determination of quantitative variation of phytoplankton pigments was done by spectrophotometric analysis (APHA, 1995). The chlorophyll a, chlorophyll b and pheophytin content of the extracts were determined by measuring optical density (APHA, 1995) using spectrophotometer. For the estimation of chlorophyll, the water sample was filtered through GF/C glass fibre filter paper, using a filtration apparatus fitted with vacuum pump. A thin bed of magnesium carbonate ($MgCO_3$) was applied to the filter paper. The filter paper containing the pigments were transferred to a clean beaker and added 5ml of 90% acetone, and the beaker was wrapped with aluminium foil, kept overnight at 4^oC in a refrigerator. The contents were macerated and made up the extract solution to 10ml .The absorbance at wave lengths of 750, 665, 645, 630 and 450 nm of the resulting acetone. Pheopigments were measured by adding 2 drops of 0.5N HCl to the same sample and measurement of absorbance were performed at wavelengths 750nm and 665 nm. For the estimation of carotenoids, the above procedure was followed and the absorbance of the pigment extract was measured at wave lengths 510 and 480nm.

Estimation of primary productivity

Light and dark bottle method (APHA, 1995) was used for the estimation of primary productivity. The "Winkler" method of determining dissolved oxygen is normally used in the 'light and dark bottle' technique for studying production rates.

2.2.8 Secondary Production

Zooplankton

The samples were taken from subsurface water using standard net having mouth area $0.07m^{2,}$,70 cm long. Maximum samples were collected at the cod end collecting tube. The sample which remained on the wall of the net was washed with water and transferred into the preservation bottles. The mesh size of 0.2mm of monofilament nylon is usually used for collecting zooplankton for taxonomic and productivity studies. In addition to the mesh size, the type, length and mouth area of the net, towing speed, time of collection and type of haul will determine the quality and quantity of zooplankton collected. The zooplankton collections can be made by horizontal, oblique and vertical hauls. In the horizontal sampling the net is towed at a slow speed usually for 10 minutes. The towing speed of the net should be such that the maximum amount of water enters through the mouth of the net for better filtration and gear used can withstand the strain. After fixation, the zooplankton are transferred and stored in airtight containers with sufficient quantity of preservative. While transferring, due care should be taken so that no part of the zooplankton sample is lost. The counting should be done under the microscope using Sedge wick rafter cell and when the specimen of a particular group is seen, a tally mark is made on the sheet. Zooplankton sampling and analysis were done following the

standard method (UNESCO, 1968; IOBC, 1969). Samples were preserved in 5% formalin (Goswami, 2004). Analysis of the zooplankton samples was done by group wise sorting. At first sub sampling was done after centrifuging the settled samples and the numerical abundance of each group in the entire 15 stations was computed and recorded.

2.2.9 Teritiary production

Fish Landing Centres

Data of fish landings of economically important food fishes adjacent to the sampling locations sited below were assessed seasonally from the following landing centres by stock assessment made through vendors.

1. Ernakulam market
2. Champakkkara, Aroor
3. Chempu
4. Vaikom
5. Vypin
6. Varappuzha Jetty
7. Perumbalam

Gut content Analysis

The study of the feeding habits of fish and other animals based upon analysis of stomach content has become a standard practice (Hyslop, 1980). The specimens for gut content analysis were obtained from the respective sites during the sampling period. The fishes were brought to the laboratory, the specimens were dissected and their stomachs were dissected and their stomachs removed and preserved in specimen bottles containing 4% formalin. In the laboratory, total weights of the stomachs and stomach

contents were determined. Some of the stomachs were used to study food composition and selection. The stomachs were dissected and the content emptied into a petridish and they were washed well in 10 ml of water. The larger invertebtates such as chironomids and oligochaets, larvae were isolated counted and weighed. The rest of the material which constituted of detritus and plankton was thoroughly mixed with 10 ml of water in a beaker. A subsample was pipette out in a Sedgewick rafter cell which carries a volume of 1ml. The food items were then enumerated under a compound microscope. The analysis was made in triplicate. The occurrence of each food item was scored and then converted to a percentage by multiplying the ratio of the number of times an item occurred to the total number of guts analyzed by a hundred. The percentage abundance of each food item was also computed by multiplying the ratio of the number of a particular item in the stomach to the total number of items in the stomach by a hundred. The plankton samples taken from different locations where fish were sampled were identified and enumerated using a compound microscope. The organisms found in the food were identified to generic level and in few cases to species level wherever possible. The percentage occurrence and abundance of each item in the samples were analyzed in a similar way.

Proximate composition of the selected fishes

All biochemical analyses were carried out on fish samples previously oven dried at 60ºC until constant weight and finely powdered with a pestle (Pulverisette2, FRITSCH).

Total Proteins

Proteins in water were hydrolysed with IN NaOH at 80°C for 30 minutes. Colour developed using Copper reagent and Folin-Ciocalteu

reagent (Lowry et al, 1951). The absorbance was then measured at 750 nm using UV - Visisble spectrophotometer.

Total Carbohydrates

Carbohydrates were estimated by the phenol-sulphuric acid method (Dubois et al., 1956). The samples were hydrolysed with IN conc. H_2S0_4 in 1: 1 ratio at 100^{o}C for 1 hour and cooled at room temperature and filtered. To l ml of the aliquots, add I ml of 5% phenol and concentrated H_2S0_4, cooled the test tube and measured absorbance at 490 nm using UV Visible spectrophotometer (Genesys 10 UV).

Total Lipids

Lipids were extracted from the sediments and particulate matter according to the method of Bligh and Dyer, 1959. To 10 ml sample, 10 ml chloroform-methanol (2: 1 v/v) mixture and 20 ml of aqueous NaCI were added in separating flask and after thorough shaking. The preparation was allowed to stand for 30 minutes from the clean biphasic layer formed, the lower phase was removed and the same quantity of chloroform was added to make up the volume. This extract was dried in a vacuum desiccator, over silica gel and added 0.5 ml concentrated H_2S0_4, boiled maintaining in a water bath at 60°C. After cooling to room temperature, 5ml vanillin reagent was added and allowed to stand for 30 minutes. The absorbance of pink color developed was measured at 520 nm using spectrophotometer.

The fishes collected were virtually of the same size and sex as variability in size stands to affect the proximate composition and the mineral elements concentration. All the samples were collected fresh and refrigerated below 40^{0}C prior use.

Moisture content

Estimation of moisture content was carried out by drying the pre-weighed wet samples at 60 °C until a constant weight was obtained. The difference in weight was calculated and expressed as percentage moisture content of the sample. Percentage was calculated by the following formula.

Moisture % = Weight of tissue-Dry weight of tissue/Wet weight of tissue ×100

The dried samples were finely powdered using mortar and pestle and stored in desiccators for further analysis.

Ash%

Ash%= Weight of dry samples/original weight of the sample taken x 100

2.2.10 Statistical Analysis

Seasonal and spatial variations in water and sediment quality parameters were examined by Two way ANOVA without replication (Microsoft Excel, 2007). Pearson correlations analysis was carried out to find out the interrelations between different parameters (SPSS 13). PRIMER was used for statistical interpretation of data. In representative stations Multi dimensional Scaling (MDS) analysis was carried out to see species clustering / specificity using Plymouth routine in Marine Environmental Research (PRIMER- Clarke and Glorey, 2001). The main goal of the MDS is to detect meaningful dimensions underlying that allow the researcher to explain the observed similarities or dissimilarities between the factors, both biological and physico chemical. MDS helps to arrange plankton species abundance at different stations in a space so as to reproduce similarities. As a result it could explain the distances in terms of dissimilarity between species occurring in different stations. Technically it uses a function minimization algorithm that evaluates different

configurations with the goal of maximizing the goodness of fit or minimizing the lack of fit. Diversity is the precise expression of how individuals of a particular community are distributed in subsets of groups. To analyze changes in plankton community due to environmental influence relating seasons following diversity indices were also used.

Species Richness (Margalef, 1968)

Species richness is the number of different species in a particular area is calculated by

$$\mathbf{D= (S-1) \log e^{N}}$$

S is the number of species and N is the total number of individuals of all the species in the sample.

Species evenness (Heips, 1974)

Species evenness is the relative abundance with which each species are represented in an area calculated by

$$\mathbf{E= e (H(S) - 1/S-1)}$$

H(S) is the species diversity in bits of information per individual and S is the number of species.

Species diversity (Shannon and Wiener, 1963)

The advantage of this index is that it takes into account the number of species and the evenness of the species. The index is increased either by having more unique species or by having greater species evenness.

$$\mathbf{H(S) = -\sum [Pi (log2\ Pi)]}$$

Pi= ni /n (proportion of the sample belonging to the i^{th} species.

Chapter 3

GENERAL HYDROGRAPHY AND SEDIMENT CHARACTERISTICS

Contents

3.1 Intoduction

Environmental factors play a major role in shaping the plankton community and consequently changes in the distribution of biological communities are related to physical and chemical characteristics of the water column. Trophic status of an aquatic ecosystem is controlled by the hydrographic and sediment characteristics and the variations in these parameters bring about drastic changes in the community structure of fauna and flora. Knowledge on the various aspects of the physico-chemical parameters of the estuary is essential for assessing the water quality and various biogeochemical processes controlling the distribution and abundance of various species of organisms. Physico chemical variables such as salinity dissolved oxygen, nutrients and major elements either individually or collectively influence the abundance and distribution of phytoplankton production which in turn affect the secondary and tertiary production.

Interactions between the sediment and the water column play an important role in regulating phytoplankton production and the extent of bottom water hypoxia/anoxia (Kemp and Boynton, 1992; Madhu et al., 2007).

3.2 Results

Water and surface sediment samples collected from the selected stations of Cochin backwaters were analysed for various physico-chemical parameters. General hydrographic variables, nutrients such as nitrate, nitrite, ammonia, phosphate, silicate and iron were determined in the water samples taken from the CBW. Data regarding rainfall and tides were also collected. Seasonal average concentration of various hydrographic parameters and their spatio-temporal variations were also determined. Characteristics of sediment like pH, Eh, texture, concentration of biochemical constituents such as total protein, total carbohydrate, total lipids, chlorophyll pigments, tannin and lignin were also estimated. Along with this, nitrogen fractionation was also done for the detailed knowledge on the concentration of nitrate, nitrite, ammonia and total nitrogen present in the sedimentary environment. Fractionation of phosphorous in sediments was carried out to evaluate the enrichment of this nutrient element in the study area.

3.2.1 General hydrographic parameters

The variations of general hydrographic parameters estimated in surface and bottom layers are furnished in tables 3.1 and 3.2 respectively.

Rainfall

Total rainfall of 367mm was recorded from January 2009 to April 2010. During POM 08, measured rainfall was 18mm and in PRE 09, it was observed to be 154mm. However MON 09 exhibited a rainfall of 180 mm. During POM 09 and in PRE 10, it was 7and 8mm respectively. Rainfall data were obtained from the meteorological Centre, Trivandrum (Govt. of India).

Tide

Tide data was collected from Cochin Port Trust (Govt. of India). At the time of collection during POM 08 high tide was observed. During PRE 09, MON 09, POM 09 and PRE 10 low tide was recorded.

Atmospheric - Temperature

Spatiotemporal variation and average value for atmospheric temperature is depicted in figure 3.1 and table 3.1. POM 08 displayed atmospheric temperature values varying from 25 to 33.2^{o}C with an average of 29.87±2.31 ^{o}C. It could be noticed that in PRE 09, values ranged between 30 and 36.16^{o}C (average: 33.28±1.98^{o}C). MON 09 recorded an average temperature of 31.14±2.33^{o}C and ranged from 26 to 34 ^{o}C. However the exhibited variation during POM 09 was from 26 to 39 ^{o}C with an average of 29.87±3.78^{o}C. The estimated average atmospheric temperature was 31.23±1.76 ^{o}C (PRE 10) and recorded variation was from 29 to 34 ^{o}C. ANOVA (table 3.1) revealed that atmospheric temperature showed significant seasonal variation ($p < 0.01$) only.

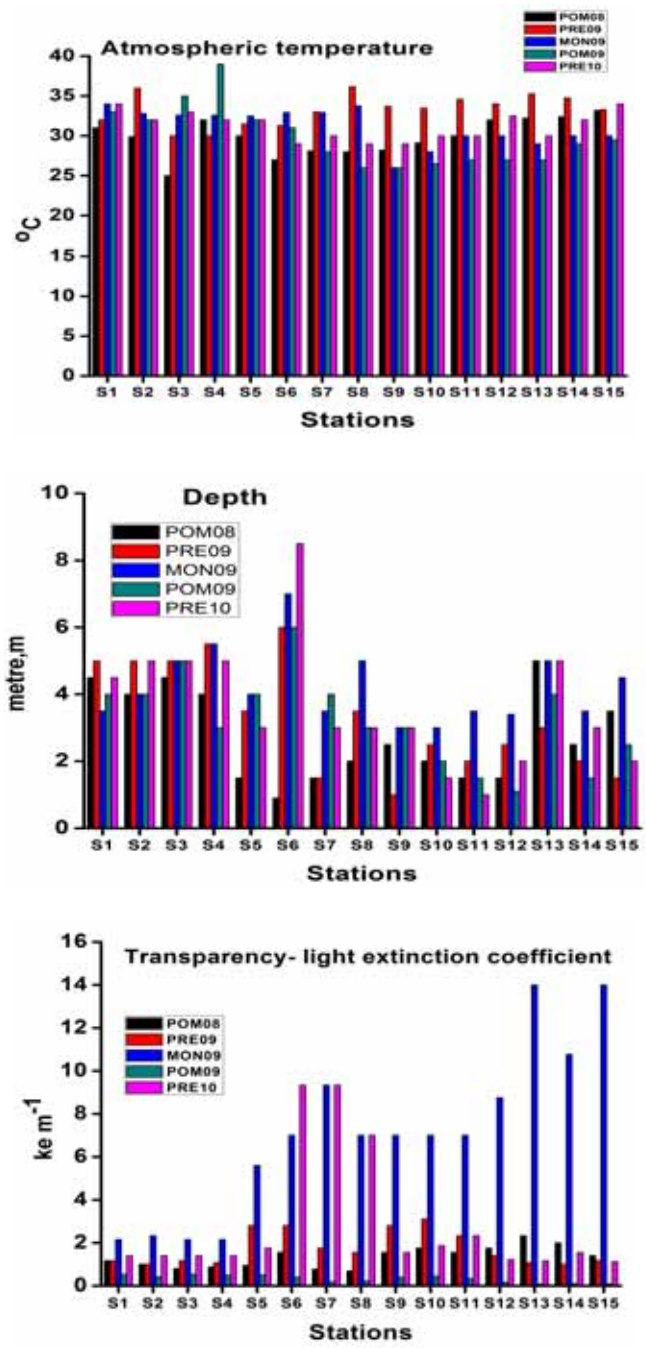

Figure 3.1 spatial and seasonal variation in atmospheric temperature, depth of stations and transparency

Depth

Figure 3.1 provides the variation in depth throughout the investigation period. Out of the 15 sampling stations, during POM 08, an average depth of 2.76±1.36m was recorded and it varied from 0.9 to 5m (table 3.1). In PRE 09, average depth was found to be 3.3±1.63m and it ranged between 1 and 6m. MON 09 exhibited an average depth of 4.22±1.1m and it ranged between 3 and 7m. Measured depth during post MON 09 ranged from 1.1 to 6m (average: 3.24±1.37m). However, PRE 10 revealed an average depth of 3.63±1.9m and it varied from 1 to 8.5m.

Transparency- light extinction coefficient

Transparency recorded an average of 1.34±0.49kem^{-1} and varied from 0.7 to 2.3kem^{-1}, during POM 08 (table 3.1). However in PRE 09, average value was found to be 1.75±0.79kem^{-1} and observed values ranged between 1 and 3.11m. MON 09 found to exhibit values varying from 2.15 to 14 kem^{-1} with an average of 7.08±3.91kem^{-1}. The observed variation in transparency during POM 09 was from 0.07 to 0.54kem^{-1} (average: 0.33±0.17kem-1). In the present investigation, PRE 10 recorded values ranging between 1.12 to 9.33 kem^{-1} with an average of 2.92±2.97kem^{-1}. ANOVA revealed that transparency exhibited only significant seasonal variation ($p<0.01$). Spatiotemporal variation in transparency is represented in figure 3.1.

pH

Spatiotemporal variation and average values of pH in surface layers of the water column is furnished in table 3.1 and figure 3.2. Measured values of pH (surface waters) during POM 08 ranged between 7.4 and 8.1 with an average of 7.65±0.19. Meanwhile, in PRE 09, the average value for this variable was found to be 7.52±0.34 and the exhibited variation was from 7 to 8.1. Observed values of pH of the surface waters during MON 09

varied from 7.1 to 7.9 (average: 7.54±0.24). During POM 09, average pH recorded was 7.55±0.37 and it varied from 6.8 to 8.1. However during PRE 10, it varied from 6.8 to 8.1 (average: 7.48±0.39).

Average values of pH and its spatiotemporal variation in bottom layers of the water column is furnished in table 3.2 and figure 3.2. During POM 08 (bottom waters), values of pH varied from 7.4 to 8 with an average of 7.68±0.20. In PRE 09, pH ranged between 7.2 and 8.4 (average: 7.7±0.36). Average value of pH was measured to be 7.55±0.21 and it ranged from 7.1 to 7.9 (MON 09). In the case of POM 09, pH of bottom layers varied from 6.9 to 8 (average: 7.59±0.33) and in PRE 10, it varied from 6.7 to 8.2 (average: 7.42±0.44).

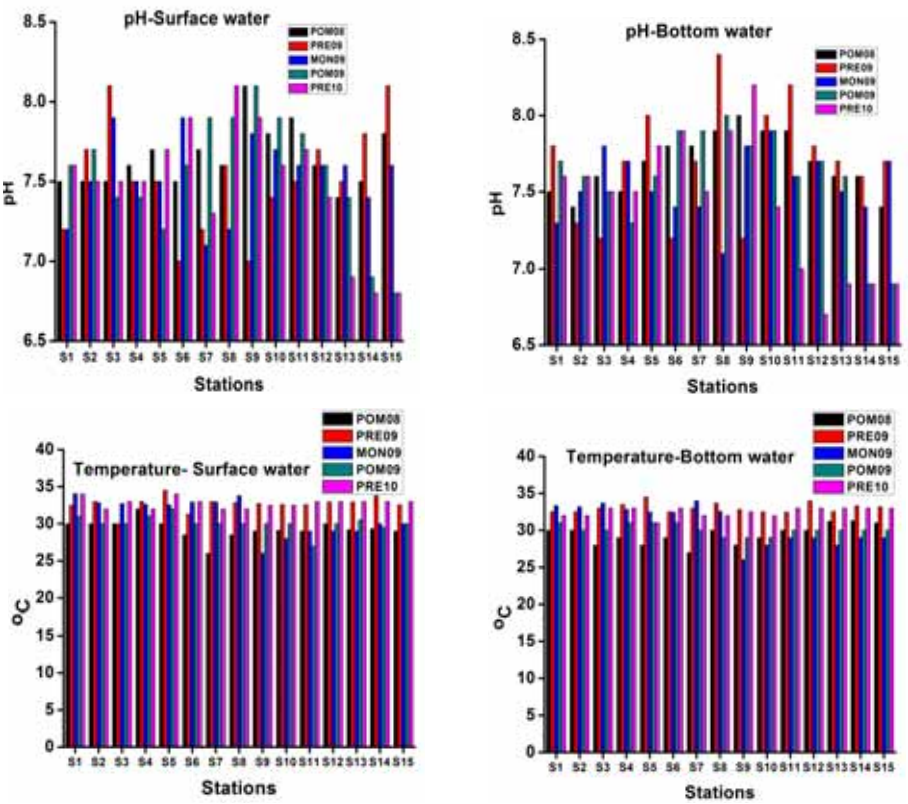

Figure 3.2 Spatial and seasonal variations in pH and temperature of water column

Water - Temperature

Seasonal variation in temperature of both surface and bottom waters is depicted in figure 3.2. Surface waters recorded values for temperature varying from 26 to 32°C (average: 29.30±1.26°C), during POM 08 (table 3.1). Meanwhile, PRE 09 exhibited an average of 32.68±1°C with values ranging between 30 and 34.5°C. The measured temperature of surface water ranged from 26 to 34.06°C with an average value of 31.02±2.44°C during MON 09. During POM 09 values for surface water temperature varied from 27 to 32°C (average: 30.06±1.04°C) and in PRE 10, it varied from 32 to 34°C (average: 32.8±0.65°C).

During POM 08, average temperature of bottom layers was 29.43±1.30°C and it varied from 27 to 31.3°C (table 3.2). In PRE 09, temperature of bottom layers ranged between 32.44 and 34.5°C with an average of 33.06±0.62°C. However the observed values of temperature in bottom waters, during MON 09, ranged from 26 to 34°C (average: 30.83±2.60°C). During POM 09, temperature of bottom waters varied from 29 to 31°C with an average of 30.06±0.70°C and in PRE 10, it varied from 31 to 33°C (average: 32.5±0.62°C).

Dissolved oxygen (DO)

During POM 08, dissolved oxygen (surface waters) varied from 3.74 to 6.34mg/L with an average of 5.3±0.7mg/L (table 3.1). In PRE 09, DO ranged between 3.59 and 6.18mg/L (average: 5.07±0.66mg/L). It recorded an average content of 6±0.5mg/L with a variation from 5.24 to 6.76mg/L during MON 09. During POM 09, it ranged from 3.32 to 6.69mg/L and recorded an average of 5.4±1.1mg/L. In the present study, PRE 10 an average concentration of 5.49±0.99mg/L and the observed DO

content found to range between 3.96 to 6.95mg/L. The seasonal average of DO content in the study area is furnished in table 3.1. The variation in concentration of DO in surface and bottom water is depicted in figure 3.3.

In bottom waters of the study area during POM 08, DO varied from 3.28 to 6.22mg/L, with an average of 5.05±0.80 mg/L (table 3.2). In PRE 09, DO exhibited an average content of 4.58±0.88mg/L and ranged from 2.61 to 5.88 mg/L. During MON 09, the value varied from 2.24 to 6.38mg/L (average: 5.23±1.06 mg/L). However, recorded DO content during POM09 ranged between 3.1 and 6.1mg/L with an average of 4.98±1.02 mg/L. The average DO content estimated during PRE 10 was observed to be 5.51±0.95mg/L, and its content during this period ranged between 3.48 and 6.53 mg/L.

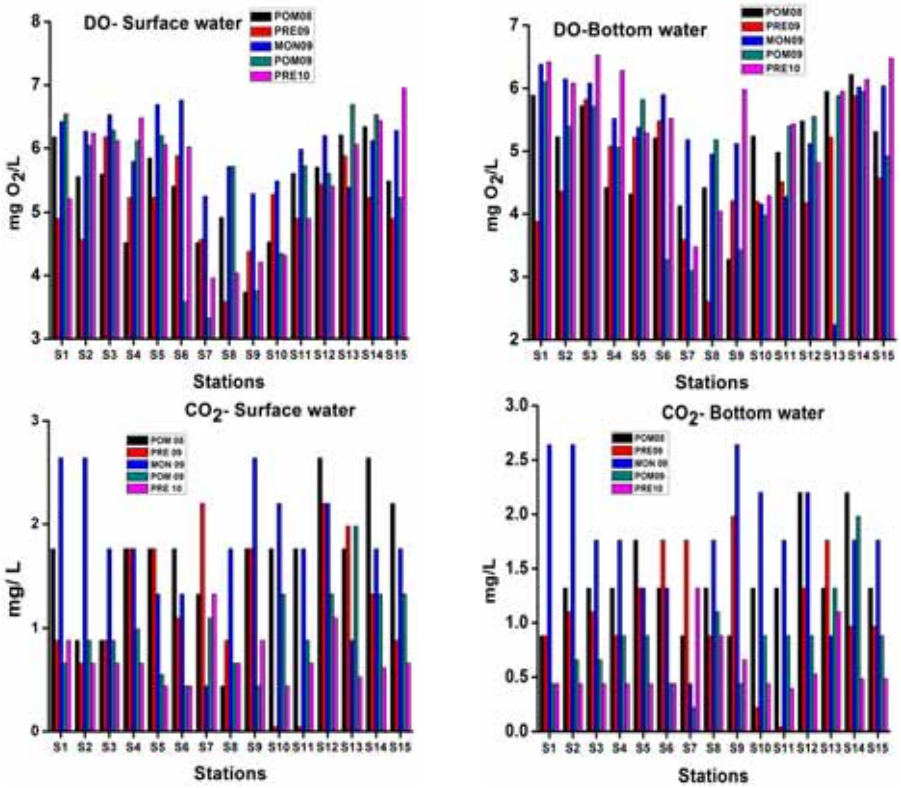

Figure 3.3 Spatial and seasonal variations in DO and CO_2 in water column

Carbon Dioxide

Spatiotemporal variation and average concentration of CO_2 in surface layers of the water column is furnished in table 3.1 and figure 3.3. Content of free carbon dioxide (surface waters) during POM 08 varied from 0.44 to 2.64mg/L with an average of 1.67±0.60mg/L. In PRE 09, CO_2 exhibited an average of 1.2±0.70 mg/L and ranged between 0.044 and 2.2 mg/L (figure 3.3). Concentration of CO_2 recorded an average of 1.7±0.6mg/L and ranged between 0.4 to 3.0mg/L, during MON 09. However, during POM 09, it ranged from 0.44 to 1.98mg/L (average: 0.98±0.04mg/L). Present study revealed that during PRE 10, the average CO_2 content was found to be 0.7±0.2mg/L and exhibited variation was from 0.44 to 1.32mg/L.

Average values of pH and its spatiotemporal variation in bottom layers of the water column is furnished in table 3.2 and figure 3.3. It was recorded that during POM 08, CO_2 (bottom waters) varied from 0.88 to 2.2mg/L (average: 1.0±0.40mg/L). In PRE 09, CO_2 recorded an average content of 1.0±0.5 mg/L and it ranged from 0.04 to 2.0mg/L. During MON 09, it found to vary from 0.4 to 3.0 mg/L with an average of 2.0±0.6mg/L. During POM 09, the average concentration was observed to be 0.8±0.4 mg/L and exhibited a variation from 0.22 to 1.98mg/L. The recorded content of CO_2 during PRE 10 ranged between 0.4 to 1.3mg/L (average: 0.06±0.2mg/L).

Biochemical oxygen demand (BOD)

Surface waters of the study area during POM 08 recorded BOD values varying from 0.22 to 6.2mg/L (figure 3.4) with an average of 2.4±1.73 mg/L (table 3.1) Meanwhile, PRE 09 recorded values ranging between 0.62 and 5.41mg/L (average: 3.64±1.56 mg/L). BOD recorded an average value of 2.02±1.54 mg/L during MON 09 and it ranged between

0.29 and 4.98mg/L. Average value BOD was estimated to be 2.54±1.85 mg/L and it ranged from 0.16 to 6.24mg/L during POM 09. During PRE 10, values of BOD ranged between 0.64 to 5.76mg/L with an average of 4.11±1.73 mg/L.

Spatiotemporal variation in BOD (bottom layers) of the water column is depicted in figure 3.4. It was found that during POM 08, BOD values in bottom waters varied from 0.14 to 5.96mg/L with an average value of 2.24±2.02mg/L (table 3.2). In PRE 09, it recorded a variation ranged between 0.5 to 5.98mg/L (average: 3.53±1.58mg/L). Meanwhile, MON 09 recorded an average BOD value of 2.28±1.53mg/L and exhibited variation from 0.18 to 5.1mg/L. The estimated average during POM 09 was 2.3±2.3mg/L, and the observed values ranged from 0.16 to 6.88g/L. PRE 10, value ranged between 0.64 to 6.72mg/L (average: 4.4±1.8mg/L). (ANOVA) displayed highly significant seasonal and spatial variation ($p<0.01$) for both surface and bottom layers.

Salinity

Seasonal and spatial variation in salinity of surface and water is furnished in figure 3.4. During POM 08, salinity in surface waters varied from 3.47 to 32 psu with an average of 17.11±9.37 psu (table 3.1). In PRE 09, exhibited an average value of 10.53±8.93psu and ranged from 1.57 to 28.89 psu. Estimated salinity during MON 09 varied from 3.47 to 17.52 psu with an average of 11.12±10.10 psu. However during POM 09, it ranged between 1.28 and 29.93 psu (average: 11.12±10.08psu). While in PRE 10, it ranged between 0.71 to 29.46 psu with an average of 8.82±8.11 psu.

During POM 08, salinity in bottom waters varied from 3.47 to 33.72 psu with an average value of 19.01±9.83psu (table 3.2). The observed average value for salinity during PRE 09, ranged from 1.57 to 29.52psu (average: 12.09±8.5 psu). Average salinity estimated during MON 09 was

found to be 9.12±6.67 psu and revealed a variation from 3.47 to 24.32psu. During POM 09, salinity ranged from 1.28 to 31.38psu and it displayed an average of 11.33±9.43psu. But during PRE 10, it ranged from 0.59 to 33.5 psu and recorded an average of 11.52±11.22psu.

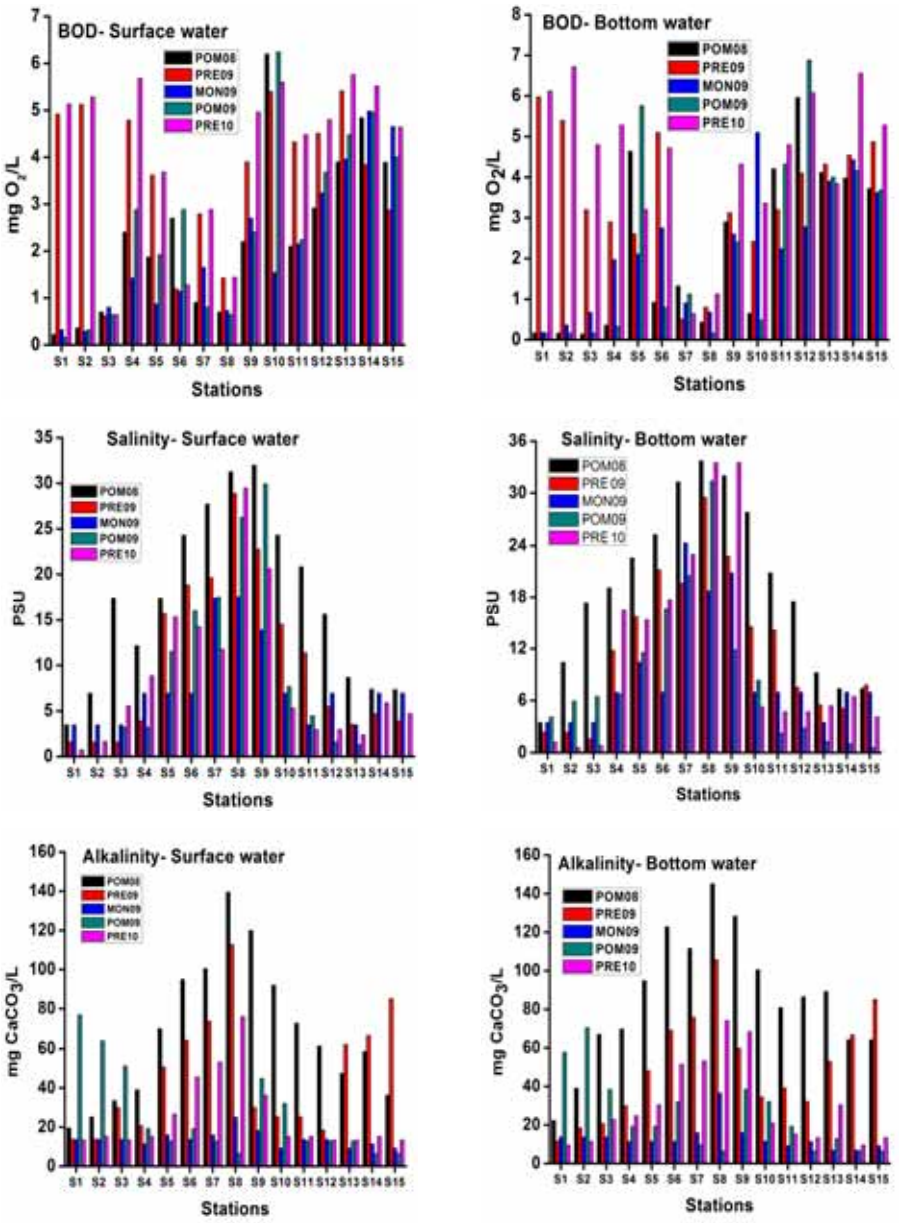

Figure 3.4 Spatial and seasonal variation in BOD, salinity and alkalinity in water column

Alkalinity

Seasonal average values for alkalinity of water samples (surface and bottom layers) is depicted in tables 3.1 and 3.2 respectively and their spatiotemporal variation is represented in figure 3.4. During POM 08 alkalinity in surface waters varied from 19.53 to 140mg$CaCO_3$/L (average: 67.33±35.82 mg$CaCO_3$/L). In PRE 09, alkalinity ranged between 13.8 to 112.7 mg$CaCO_3$/L with an average of 16.15±30.04 mg$CaCO_3$/L. The recorded average for this variable 13.83±4.08 mgCaCO3/L during MON 09 ranged between 9.12 to 25.08 mg$CaCO_3$/L. It was observed that during POM 09 value ranged from 6.4 to 76.8mg/L and the recorded average was 26.02±22.62 mg$CaCO_3$/L. Meanwhile, PRE 10 represented the minimum of 13.3 and maximum of 76mg$CaCO_3$/L (average: 25.3±19.10 mg$CaCO_3$/L).

In the present investigation, POM 08 revealed an average alkalinity value of 85.74±33.22 mg$CaCO_3$/L (bottom waters) and observed variation was from 22.32 to 145.08 mg$CaCO_3$/L. Meanwhile PRE 09 displayed an average of 49.98±26.96 mg$CaCO_3$/L and this hydrographic variable ranged between 11.5 and 105.8 mg$CaCO_3$/L. During MON 09, alkalinity ranged between 6.84 to 36.48 mg$CaCO_3$/L (average: 13.22±7.01mg$CaCO_3$/L). Alkalinity displayed an average of 24.96±19.73 mg$CaCO_3$/L during POM 09 and it ranged from 6.4 to 70.4 mg$CaCO_3$/L. Estimated value during PRE 10, ranged between 9.5 and 74.1 mg$CaCO_3$/L and displayed an average of 29.89±21.60 mg$CaCO_3$/L. Analysis of variance (ANOVA) revealed only highly significant seasonal variation ($p<0.01$) for surface waters. However, bottom waters exhibited both seasonal and spatial variation ($p<0.01$). During

MON 09, the values were lower compared to other seasons in both surface and bottom waters of the study area (figure 3.4).

3.2.2 Nutrients in water column

The spatiotemporal variation and average concentration of the estimated nutrients in surface and bottom layers of the water column is depicted in figures 3.5 and 3.6 and tables 3.1 and 3.2.

Ammonia-N

Surface water samples collected during POM 08 exhibited an ammonia content varying from 0.07 to 0.38µmol/L with an average of 0.16±0.09 µmol/L. Concentration of ammonia ranged between 2.6 and 356.1µmol/L and the estimated average concentration was found to be 59.24±90.62 µmol/L, in the PRE 09 period. The observed variation was 4.72 to 98.09µmol/L during MON 09 (average: 36.21±22.14µmol/L). Average ammonia content (POM 09) was found to be 38.89±44.49µmol/L and the observed range for this variable was from 1.57 to 136.70µmo/L. During PRE 10 value ranged between 6.69 to 410.50µmol/L (average: 74.69±100µmol/L).

During POM 08, concentration of ammonia in bottom waters varied from 0.02 to 0.96µmol/L and recorded an average of 0.19±0.22µmol/L. In PRE 09, ammonia ranged between 1.57 and 82.73µmol/L (average: 28.38±27.19µmol/L). During MON 09, concentration of ammonia recorded an average of 42.29±26.38 and it varied from 14.97 to 105.2µmol/L. During POM 09, its concentration ranged from 1.34 to 177.70µmol/L with

an average of 41.31±58.80µmol/L. While during PRE 10, concentration ranged between 7.48 and 132.80µmol/L (average: 58.62±39.66 µmol/L).

Nitrate-N

It was noticed that during POM 08 nitrate in the surface waters varied from 3 to 47.3µmol /L and recorded average of 13.58±12.78 µmol/L. In PRE 09, nitrate ranged between 2.3 to 27.2µmol/L with an average of 10.05±6.87 µmol/L. Average concentration of nitrate in surface waters of the study area, during MON 09 was found to be 30.63±70.89µmol/L and it ranged from 6.20 to 290.30µmol/L. During POM 09, value ranged from 1.2 to 15.4µmol/L and displayed an average content of 8±4.88µmol/L. While in PRE 10, concentration of nitrate varied from 0.93 to 30.50µmol/L with an average of 9.56±8.54µmol/L.

However bottom waters of the study area during POM 08 exhibited a variation nitrate concentration from 0.53 to 177.4µmol/L (average: 20.96±44.2 µmol/L). In PRE 09, nitrate ranged between 0.88 and 17.4µmol/L and recorded an average of 7.81±4.96 µmol/L. While during MON 09, its content ranged from 7.5 to 41.89 µmol/L and the estimated average was found to be 21.04±12.55 µmol/L. During POM 09,the nitrate content ranged from 2.3 to 15.6µmol/L with an average of 7.96±3.88µmol/L. Meanwhile concentration of this variable during PRE 10, ranged between 0.79 and 25.6µmol/L and displayed an average of 10.59±8.5µmol/L. Statistical analysis of variance displayed only significant spatial variation.

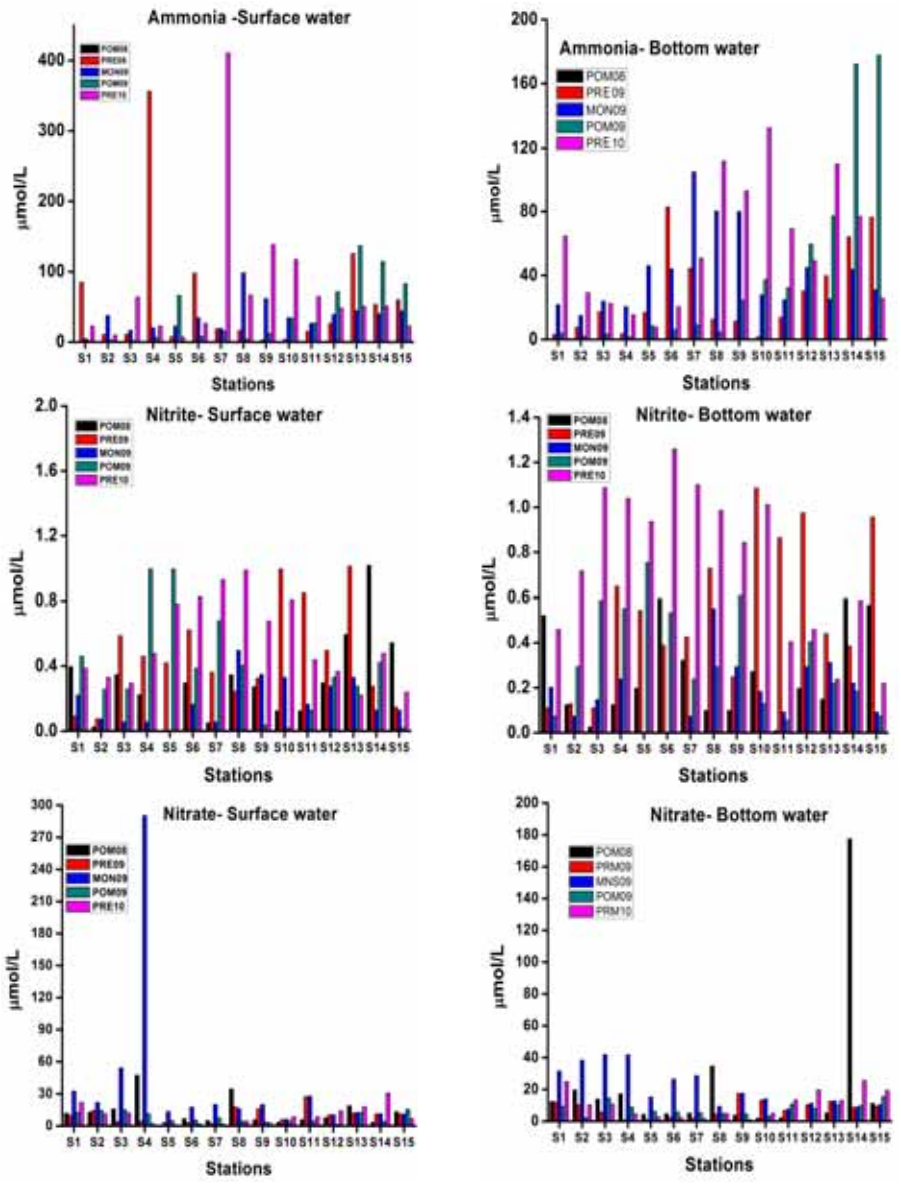

Figure 3.5 Spatial and seasonal variation in ammonia, nitrite and nitrate in water column

Nitrite

During POM 08 nitrite in the surface waters varied from 0.03 to 1.02µmol /L and the estimated average was found to be 0.33±0.25µmol/L. In PRE 09, nitrite ranged between 0.07 and 1.01µmol/L with an average

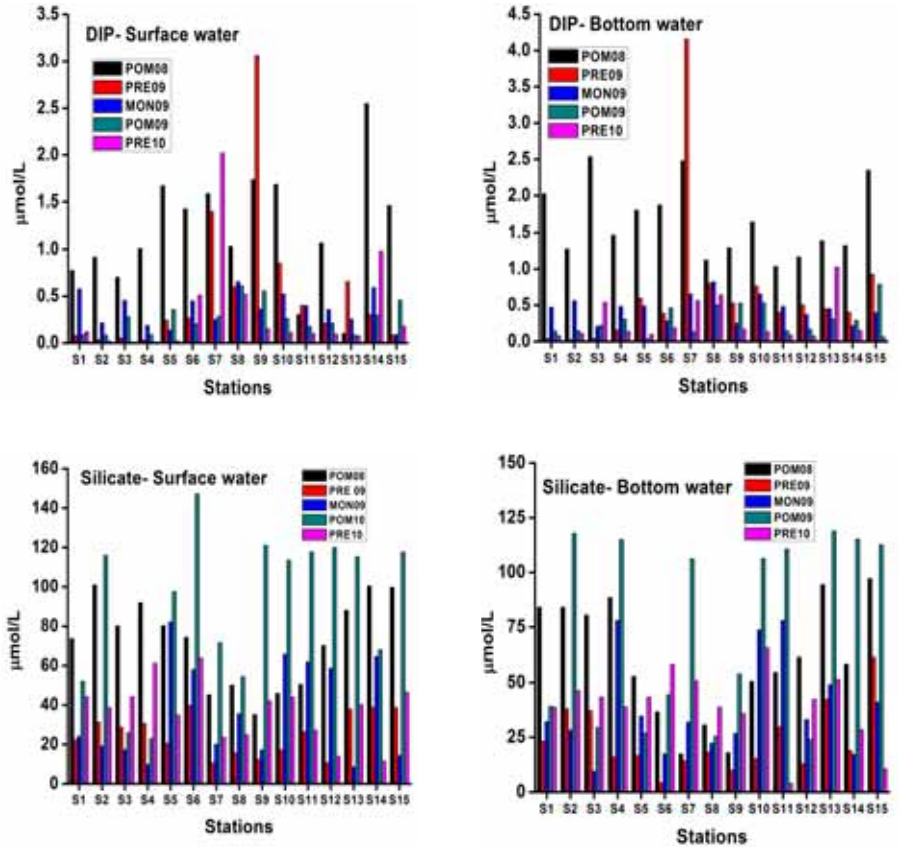
content of 0.46±0.30 µmol/L. While during MON 09, the recorded average concentration of nitrite was 0.20±0.13µmol/L and it varied from 0.05 to 0.49µmol/L. However, during POM 09, the concentration of nitrite ranged from 0.02 to 0.99µmol/L (average:0.37±0.30µmol/L). In the present investigation, concentration of nitrite during PRE 10 ranged between 0.221 and 0.986µmol/L and recorded an average of 0.54±0.25µmol/L.

While in bottom layers, the concentration of nitrite during POM 08 exhibited a variation from 0.01 to 0.59µmol/L with an average of 0.26±0.21µmol/L. PRE 09 exhibited concentration of nitrite varying from 0.11 to 1.09 µmol/L with an average of 0.53±0.32µmol/L. The estimated average concentration for this variable was found to be 0.53±0.32 µmol/L (POM 09) and it nitrite ranged from 0.11 to 1.09µmol/L. However, during MON 09 its content ranged between 0.07 and 0.55 µmol/L and revealed an average of 0.21±0.13 µmol/L. Concentration of Nitrite during PRE 10 displayed an average of 0.75±0.33 µmol/L and it ranged between 0.22 and 1.26µmol/L.

Dissolved inorganic phosphate (DIP)

Spatiotemporal variation in DIP is represented in figure 3.6. During POM 08 phosphate in the surface waters ranged between 0.10 and 2.55µmol /L and it displayed an average of 1.20±0.62µmol /L. During POM 09, it varied from 0.03 to 3.06µmol/L and exhibited an average concentration of 0.55±0.79µmol/L. The content of dissolved inorganic phosphate during MON 09 recorded an average of 0.36±0.17µmol/L and it ranged between 0.08 to 0.65µmol/L. Meanwhile, during POM 09, its content varied from 0.03 to 3.06µmol/L and the estimated average was found to be 0.55±0.79µmol/L. Average concentration of dissolved inorganic P was found to be 0.32±0.53µmol /L and it ranged between 0.01 and 2.02µmol/L (during PRE 10).

Content of inorganic phosphate during POM 08 (bottom waters) of the study area varied from 1.03 to 2.53µmol/L and recorded average of 1.65±0.50µmol/L. In PRE 09, phosphate ranged between 0.02 and 4.15µmol/L and exhibited an average concentration of 0.67±1.0µmol/L. Average concentration of phosphate during MON 09 was observed to be 0.45±0.17µmol/L and this variable ranged from 0.20 to 0.82µmol/L. While, in POM 09, the observed variation in concentration was from 0.03 to 0.78µmol/L and the estimated average was found to be 0.31±0.2 µmol /L. Concentration of DIP during PRE 10 ranged between 0.06 and 1.02µmol/L (average: 0.26±0.28µmol /L).



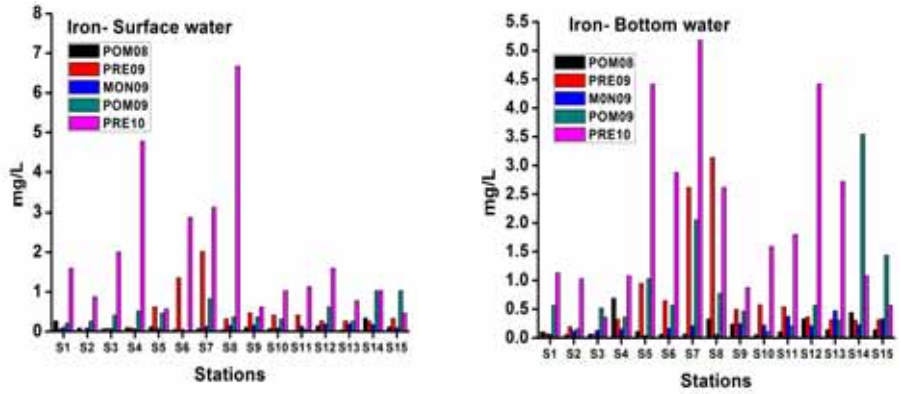


Figure 3.6 Spatial and seasonal variation in DIP, silicate and iron in water column

Silicate

Concentration of silicate (surface waters) during POM 08 ranged from 35.2 to 101µmol/L and recorded an average of 72.46±22.23µmol/L (table 3.1). It ranged between 10.54 and 39.78µmol/L, with an average of 25.43±10.67µmol/L (PRE 09). Meanwhile, during MON 09, the silicate content ranged from 8.52 to 82.16µmol/L and recorded an average of 37.1±25.03µmol/L. Average concentration of silicate during POM 09 was found to be 90.70±38.48 µmol/L and estimated concentration varied from 22.83 to 147.2µmol/L. During PRE 10, its content ranged between 11.49 to 63.91µmol/L (average: 37.37±15.11 µmol /L).

During POM 08, silicate in bottom waters varied from 17.45 to 97.08µmol/L and the estimated average was found to be 60.64±26.84 µmol/L (table 3.2). In POM 09, the concentration ranged from 4.22 to 61.45µmol/L and recorded an average of 23.88±15.11µmol/L. In the present study, during MON 09 it ranged between 9.52 and 78 µmol/L (average: 38.22±22.10µmol /L). POM 09 recorded a minimum of 23.87 and maximum of 118.9µmol/L and exhibited an average of 6.38±41.12µmol/L. Silicate concentration in bottom waters during PRE 10 varied from 3.95 to 65.52µmol/L and displayed an average of 39.76±16.08 µmol /L.

Iron

Spatiotemporal variation in concentration of iron in surface and bottom layers is furnished in figure 3.6. During POM 08, iron in the surface waters varied from 0.01 to 0.34mg/L and recorded an average 0.10±0.08mg/L (table 3.1). In PRE 09, it ranged between 0.005 and 2.02mg/L with an average of 0.46±0.53mg/L. The average concentration of dissolved Fe was 0.11±0.04mg/L and it varied from 0.052 to 0.188 mg/L, during MON 09. Exhibited variation in dissolved iron content during POM 09 was from ND to 1.03mg/L and average concentration was found to be 0.44±0.31 mg/L. During PRE 10, it ranged between 0.46 and 6.67 mg/L (average: 1.94±1.776 mg/L).

It was observed that during POM 08, iron in bottom waters varied from 0.05 to 0.69mg/L and exhibited an average of 0.19±0.18mg/L (3.2). The observed average Fe content during PRE 09 was 0.72±0.90mg/L and it ranged between 0.063 and 3.136mg/L. During MON 09, its concentration varied from 0.04 to 0.47mg/L (average: 0.20±0.12 mg/L). Meanwhile, during POM 09 its content ranged from 0.10 to 3.54 mg/L with an average of 0.84±0.90mg/L. During PRE 10, its content was found to fluctuate between 0.35 and 5.18mg/L and recorded an average of 2.11±1.53 mg/L.

3.2.3 General sediment characteristics

The average concentrations of general sedimentary parameters are furnished in table 3.3.

pH

Measured average value and seasonal variation in pH of sediments collected from the study area is depicted in figure 3.7. Values of pH during POM 08 varied from 7.3 to 7.85 (average: 7.5±0.16). PRE 09 recorded a variation from 6.98 to 8.3 with an average of 7.6± 0.37. During MON 09 it varied from 6.97 to 7.87 and recorded an average value of 7.45 ± 0.22. However, during POM 09 the observed values ranged from 6.78 to 7.88 (average: 7.52± 0.34). In the present study, PRE 10 exhibited a variation in pH from 6.65 to 8.1 (7.31 ± 0.46).

Table 3.3 General sedimentary characteristics

Parameter	POM 08			PRE 09			MON 09			POM 09			PRE 10			ANOVA (p value)	
	Min	Max	Average	Min	Max	Average	Min	Max	Average	Min	Max	Average	Min	Max	Average	Spatial	Seasonal

Redox potential (E^h)

Values of E^h during POM 08 varied from -230 to -45 (average: -107.66). Meanwhile PRE 09 exhibited a variation in E^h values from -345 to -67.5 (average: -161.5). In the case of MON 09, it ranged between -33.76 and -172.5 (average: -80.75). During POM 10, it varied from -276 to -54 (average: -129.2) and in PRM 10, the observed variation in E^h was from -290 to 20 (average: -101.8).

Texture

Spatiotemporal variation in sand, silt and clay in sediments of the study area is depicted in figure 3.7. In sediments, content of sand during POM 08 ranged between 0.89 and 92.9% (average: 47.72±33%) and clay varied from 3.88 to 51.4% (average: 26.20±16.62%) and silt ranged between 2.45 and 53.8% (average: 26.08±18.1%). During PRE 09, content of sand ranged from 1.68 to 97.88 % (average: 41.65±39%), clay ranged from 0.09 to 41.59% (average: 17.83±15%). In MON 09, sand exhibited a variation from 1.07 to 99.14% (average: 32.37±33 %); clay content recorded a variation from 0.61 to 35.02 % (average: 19.80±13.49%) and silt ranged from 0.24 to 92.59% (average: 47.82±24.19%). During POM 09 the estimated sand content in sediments ranged from 3.74 to 96.38 % (average: 44±34%), clay varied between 0.64 and 32.26% (average: 10.9±9.2%) and silt varied from 1.61 to 86.6% (average: 40±29%). While during PRE 10, the content of sand ranged between 2.93 to 90 % (average: 34.20±30.53%), clay recorded a variation from 0.33 to 40.7% (average: 22.26±12.47%) and silt ranged from 9.66 to 77.60% (average: 43.52±20.11%).

Total organic carbon (TOC)

During POM 08, Total Organic Carbon in sediments ranged from 0.88 to 5.13 % (figure 3.8) and recorded an average of 2.58±1.5%. In PRE 09, TOC varied from 0.46 to 6.02% with average: 2.51±1.98%. During MON 09, it ranged from 0.16 to 6.38 % and estimated average was found to be 2.64±2.02%. But during POM 09, TOC varied from 0.36 to 5.77 % (average: 2.64±1.83%). Concentration of organic carbon in sediments collected during PRE 10 exhibited a minimum of 0.61% and maximum of 4.98 % (average: 2.37±1.54%).

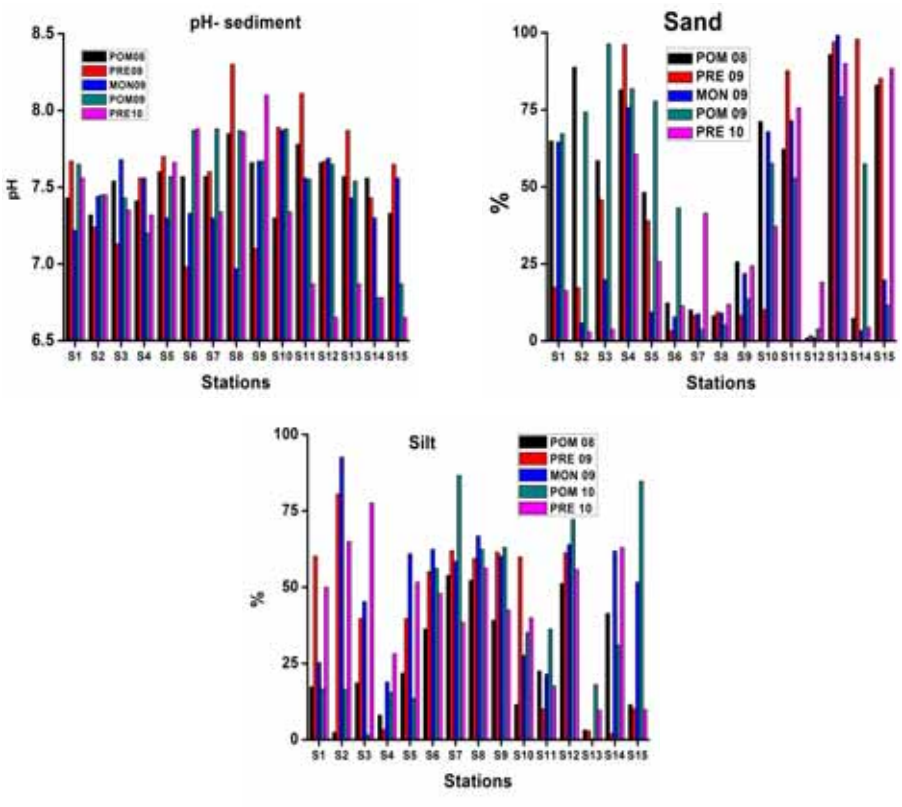

Figure 3.7 Spatial and seasonal variations in pH, sand clay and silt in sediments of the study area

Total carbon (TC)

The total carbon present in sediments during POM 08 varied from 0.39 to 6.2% with an average of 3.31±1.67% (table 3.3). In PRE 09, it varied from 0.91 to 6.87% and recorded an average content of 3.48±1.93%. While during MON 09, its concentration ranged from 0.42 to 6.97% with an average of 3.62±2.1%. During POM 09, the observed total carbon content found to vary from 1.06 to 6.6% (average: 3.56±1.99%). Average concentration of total carbon was found to be 4.07±1.9% (during PRE 10) and it ranged between 0.12 to 6.66%.

Total nitrogen (TN)

During POM 09 total nitrogen in sediments ranged from 0.10 to 0.38% (average: 0.21±0.08%). In PRE 09, it exhibited a variation from 0.05 to 0.40% and recorded average was found to be 0.18±0.11%. The recorded value of TN during MON 09, revealed a minimum of 0.02 and maximum of 0.51% (average: 0.20±0.15%). During POM 09, TN content ranged from 0.05 to 0.74 % (0.31±0.18%). In PRE 10, the concentration of TN varied from 0.12 to 1.07 % and exhibited an average content of 0.38±0.24%. Spatiotemporal variation in TN content is shown in figure 3.10.

Total sulphur (TS)

Figure 3.8 represents the spatial and seasonal variation in total sulphur in sediments. During POM 08, total sulphur content in sediments varied from 0.31 to 2.31% (average: 1.16± 0.65%). PRE 09, recorded a variation in TS content from 0.26 to 2.08% (average: 1.11±0.72%). However observed content during MON 09, it ranged from 0.16 to 2.14% with an average of 1.07±0.69%. Concentration of total sulphur during POM 09 varied from 0.18 to 2.51% and the recorded average was found to be

1.28±0.78%. PRE 10 exhibited concentrations ranging from 0.31 to 3.10% (average: 1.36±0.8%).

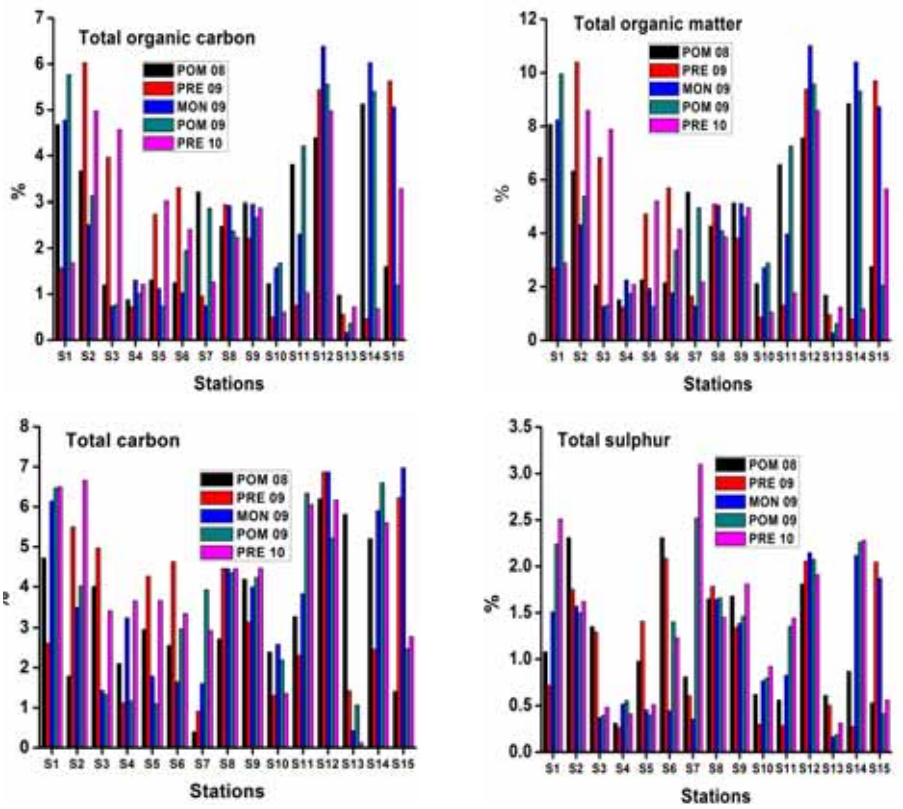

Figure 3.8 Spatial and Seasonal variations in TOC, TOM, TC, TN and TS in sediment samples

Elemental ratios

The seasonal variations of elemental ratios are depicted in figure 3.9. Present investigation recorded TOC/TS ratios ranging between 0.49 and 9.53 with an average of 3.66±2.50 (POM 08). During PRE 09, this ratio varied from 1.51 to 8.99 and recorded an average of 3.82±2.10. Average value for this ratio during MON 09 was found to be 3.63±1.02 and it varied from 2.21 to 6.30. During POM 09, TOC/TS varied from 1.56 to

6.02 (average: 3.17±1.30) and in PRE 10, it varied from 0.40 to 8.90 and estimated average value was found to be 3.72±2.42**.**

Present investigation recorded TOC/TP values (during POM 08), ranging between 0.0002 and 0.0034 (average: 0.0008±0.0008). In PRE 09, the estimated TOC/TP ratio varied from 0.0005 to 0.006 with an average of 0.002±0.0015. Observed values of TOC/TP during MON 09 varied from 0.0001 to 0.0061 and estimated an average value of 0.0026±0.0016. However during POM 09, TOC/TP varied from 0.0007 to 0.016 (average: 0.004±0.0037 and in PRE 10, it varied from 0.0003to 0.017 with an average value of 0.003±0.003.

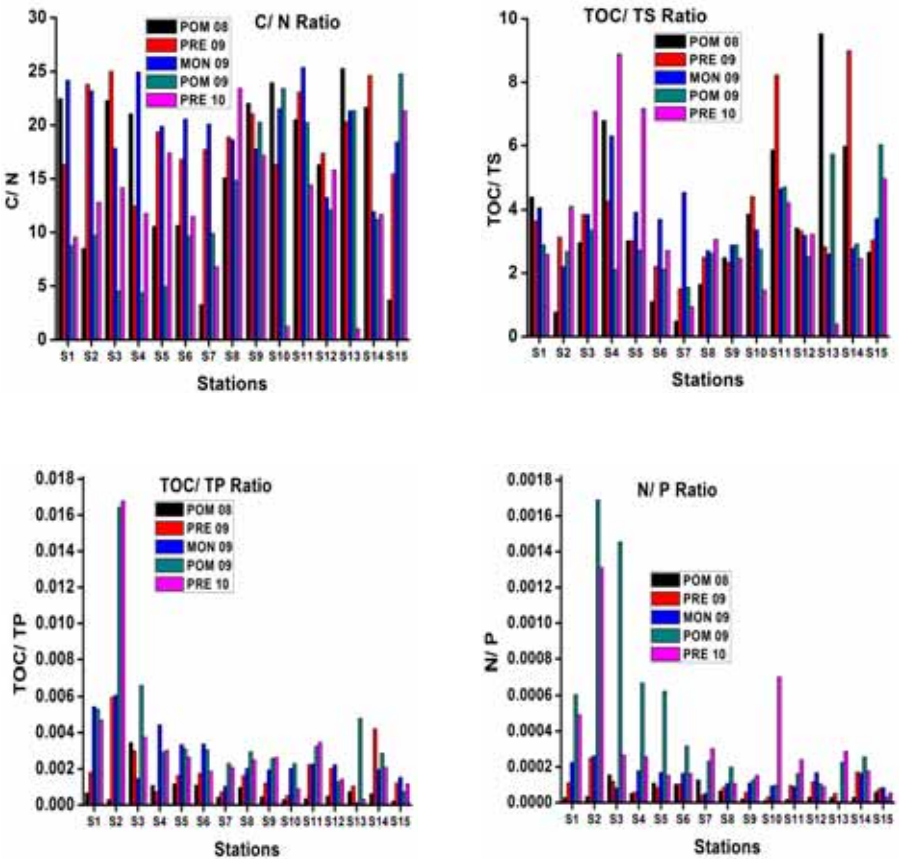

Figure 3.9 Spatial and seasonal variations in elemental ratios in sediment samples

Present study recorded N/P values during POM 08, ranging between 0.12 and 1.55 (average 0.57±0.44). In PRM 09, it varied from 0.32 to 2.50 with an average of 0.96±0.55. Observed values of N/P during MON 09 ranged from 0.05 to 2.61 and the estimated average was found to be 1.3±0.67. However, during POM 09, N/P varied from 0.29 to 16.88 (average: 4.5±4.9) and in PRM 10 it exhibited a variation from 0.53 to13.1 (average: 3.1±3.2).

3.2.4 Fractions of nitrogen in sediments

The seasonal variation of different fractions of nitrogen in sediments of the study area is depicted in figure 3.10. The average concentration various fractions of nitrogen in sediments of the study area is furnished table 3.4.

In the present study, POM 08 recorded nitrite content in sediments, ranging from 1.25 to 122mg/kg with an average of 31.32±35.14 mg/kg. The observed average concentration was found to be 16.50±17.82mg/kg during PRE 09 and it varied from 2.13 to 55.12 mg/kg. However, during MON 09, its concentration ranged between 2.25 and 121.88 mg/kg (average: 36.47±41.9mg/kg). Estimated average nitrite content in the sediments during POM 09 was 19.09±15.5mg/kg and it exhibited a variation from 2.25 to 50.63mg/kg. During PRE 10, it ranged between 2.5 and 69mg/kg and exhibited an average of 24.88±21.20mg/kg.

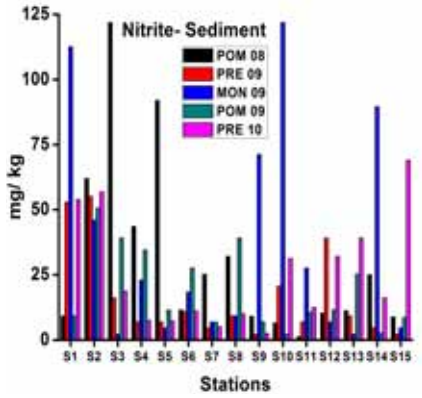
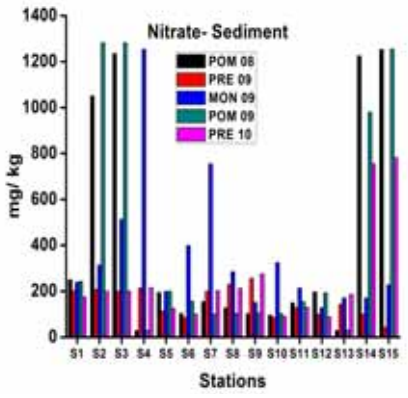
During POM 08, nitrate in sediments ranged between 28.75 and 1253mg/kg with an average of 412.98±490mg/kg. In PRE 09, concentration of nitrate exhibited an average of 153.76±65mg/kg and it varied from 42.8 to 256.25mg/kg. During MON 09, its content ranged from 128.3 to 1253.3mg/kg (average: 356.25±297mg/kg). However, the estimated average for nitrate during POM 09 was 414.11±498mg/kg and the observed concentration varied from 28.5 to 1282/kg. During PRE 10, it ranged from 87.5 to 780.8mg/kg with an average of 248.8±217mg/kg.

POM 08 recorded an ammonia content ranging between 0.75 and 3.63 with an average of 1.96±0.86mg/kg. However, in PRE 09, the observed concentration varied from 0.25 to 1.37mg/kg (average: 0.61±0.39 mg/kg). During MON 09, it ranged from 0.62 to 3.37 mg/kg and recorded an average of 1.43±0.83mg/kg. POM 09 exhibited ammonia content ranging between 0.9 and 3.6 mg/kg (average: 1.99±0.89 mg/kg). Average ammonia content in sediments was estimated to be 0.65±0.52 mg/kg (during PRE 10), and it ranged from ND to 1.62mg/kg.





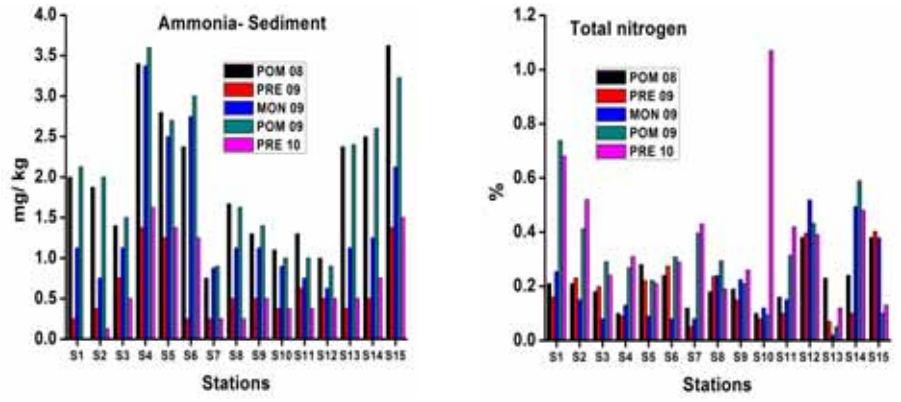


Figure 3.10 Seasonal variations in different fractions of nitrogen in sediment samples

3.2.5 Fractions of phosphorus in sediments

The seasonal and spatial variation in concentration of various fractions of phosphorous in estuarine sediments is shown in table 3.4 and figure 3.11. During POM 08, the labile P ranged between 1.16 and 24.5 mg/kg with an average of 7.32±6.16mg/kg. The Iron bound P varied from 54.48 to 3479 mg/kg and the estimated average was found to be 797.04 ± 839.61mg/kg. The calcium bound P varied from 51.32 to 1114mg/kg (average: 325.05±277.4mg/kg). The ASOP varied from 83.57 to 1611 mg/kg (average: 461±419mg/kg). The Alk-OP varied from 367.4 to 7155 mg/kg and recorded an average content of 4212±2722mg/kg. Res-P varied from 36.52 to 190 mg/kg with an average of 114.55±47.84 mg/kg. TP ranged between 944.1 to 12901 mg/kg (average: 5918± 3694mg/kg).

In the present investigation, labile P ranged between 5.41 and 191.10mg/kg with an average of 57.76 ± 51.63mg/kg (during PRE 09). The Iron bound P varied from 172 to 2247mg/kg (average: 788±512mg/kg). The Calcium bound P varied from 63 to 1193mg/kg (average: 438±323mg/kg). The ASOP varied from 77.3 to 651.79mg/kg (average: 210±148mg/kg). The Alk-OP varied from 17.9 to 1184mg/kg and estimated average concentration was 494 ± 353mg/kg. The Res-P varied from 27.3

to 270mg/kg with an average content of 114.38±77.12mg/kg. TP ranged between 586 to 5133 mg/kg and recorded an average concentration of 2104± 1175mg/kg.

It was found that during MON 09, the labile P ranged between 2.60 and 15.28mg/kg (average: 6.49±3.56mg/kg). The iron bound P varied from 120.5 to 2715 mg/kg (743.97± 681mg/kg) The Calcium bound P varied from 26.39 to 1359 mg/kg (average: 365±394mg/kg). The ASOP varied from 16.29 to 302.3mg/kg (average: 156.25±107.6mg/kg). The Alk-OP varied from 22.26 to 3242mg/kg (average: 479.60 ±793mg/kg). Res-P varied from 17.21 to 131.76mg/kg (average: 70.05± 37.06mg/kg). TP ranged between 487.3 to 4545.2mg/kg (average: 1822±1225mg/kg).

The concentration of labile P during the period POM 09 ranged between 1.18 and 17.34mg/kg (average: 4.80± 4.09 mg/kg). The iron bound P varied from 106.83 to 2720mg/kg (average: 907.95±719 mg/kg) The Calcium bound phosphorous varied from 30.12 to 1472mg/kg (average: 309 ± 405 mg/kg). The content of ASOP varied from 25.42 to 397.4mg/kg (average: 161.30±114.68mg/kg). The Alk-OP varied from 0.73 to 180.4mg/kg (average: 21.78±44.84mg/kg). The Res-P varied from 0.21 to 32.69mg/kg (average: 4.77± 8.56mg/kg). Total P ranged between 199.88 and 4097 mg/kg (average: 1410±1169mg/kg).

During the period PRE 10, the labile P ranged between 0.28 to 11.33mg/kg (average: 2.81± 2.91mg/kg). The iron bound P varied from 148.2 to 1686mg/kg (878± 437mg/kg). The Calcium bound P varied from 54.1 to 2727 mg/kg (average: 458± 719mg/kg). The ASOP varied from 54.16 to 555.4mg/kg (average: 172.34± 147.52mg/kg). The Alk-OP varied from 25.45 to 449.4mg/kg (average: 154.40± 122mg/kg). The Res-P varied from 0.73 to 40.34mg/kg (average: 11.01± 12.80mg/kg). TP ranged between 396.9 to 4349mg/kg (average: 1677± 966 mg/kg).

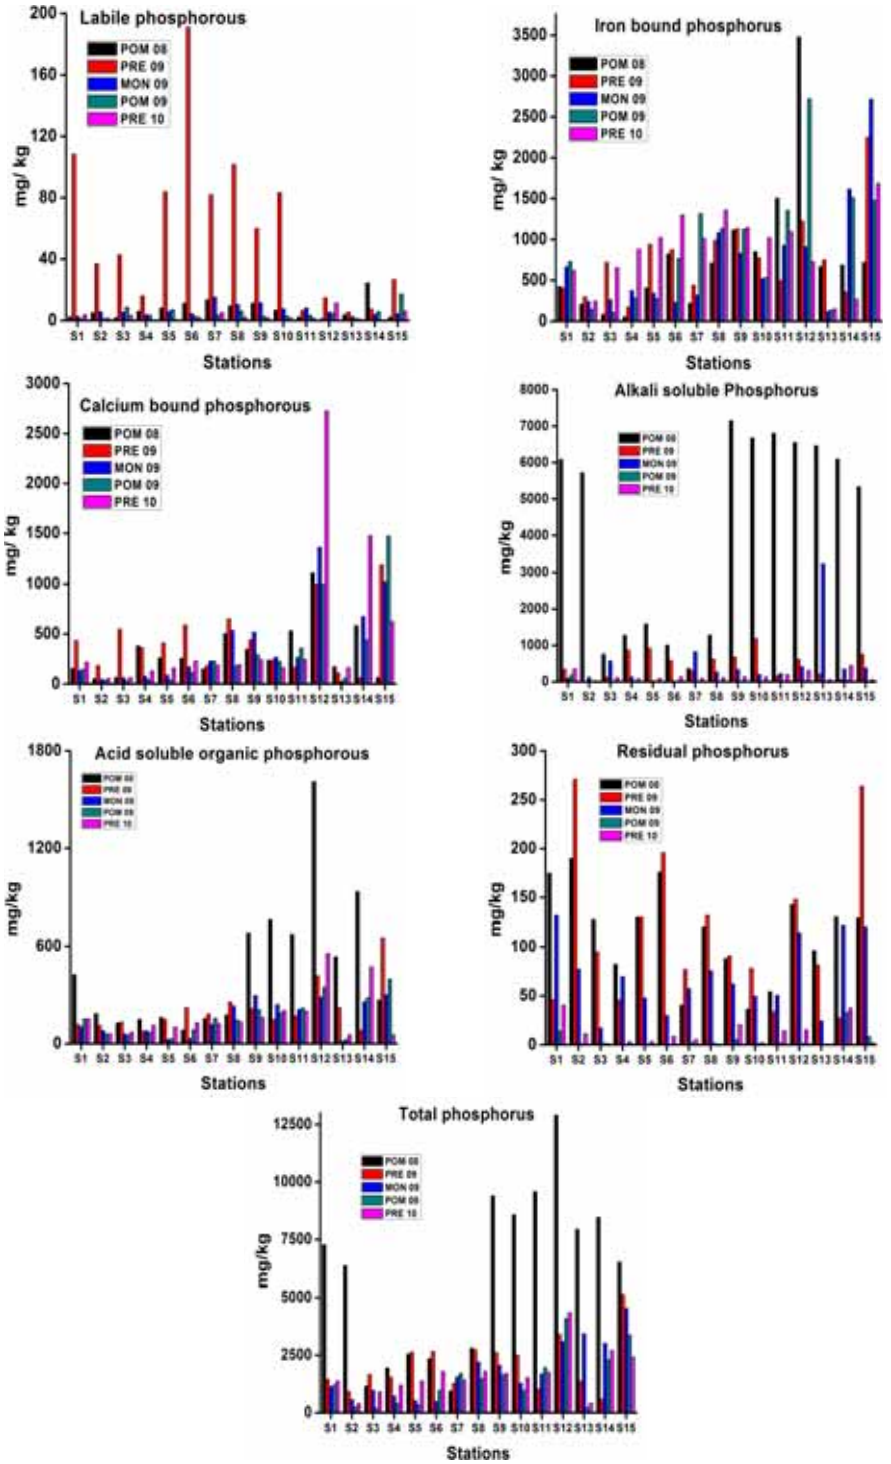

Figure 3.11 Seasonal variations in different fractions of phosphorus in sediment samples

3.2.6 Biochemical composition of sediments

Spatiotemporal variation and average concentration of various biochemical components estimated in the sediments of the study area are depicted in figure 3.12 and table 3.5.

Total protein (PRT)

It was found that during POM 08, total protein content in sediments ranged from 352.6 to 6884 mg/kg and recorded an average of 2508±1533mg/kg. However during PRE 09, it varied from 111 to 12782 mg/kg (average: 2072±3313mg/kg).The concentration of PRT during MON 09 showed minimum 156.5 and maximum 7256 mg/kg and exhibited an average content of 1337±1884mg/kg. During POM 09, it varied from 195.11 to 19420mg/kg (average: 3166±5860 mg/kg). The recorded value during PRE10 ranged from 130.9 to 14000mg/kg (average: 2604±4039 mg/kg). The seasonal variation of proteins in sediments was graphically represented in figure 3.12.

Total carbohydrates (CHO)

The seasonal variation of total carbohydrates (CHO) in the sediments is depicted in figure 3.12. During POM 08, concentration of carbohydrate in sediments ranged from 673.6 to 8072mg/kg and the estimated average content was found to be 2901±1936mg/kg. The CHO in sediments during PRE 09, varied from 943to 10491mg/kg and recorded average concentration was 2510±2393mg/kg. During MON 2009, its content ranged from 618.6 to 8887mg/kg (average: 3736 ±2725mg/kg). While during POM 09, value varied from 434.19 to 12840 mg/kg with an average of 2913 ±3690mg/kg. The concentration of CHO ranged between 657.3 and 6680mg/kg (average: 2671 ±1677mg/kg) during PRE 10.

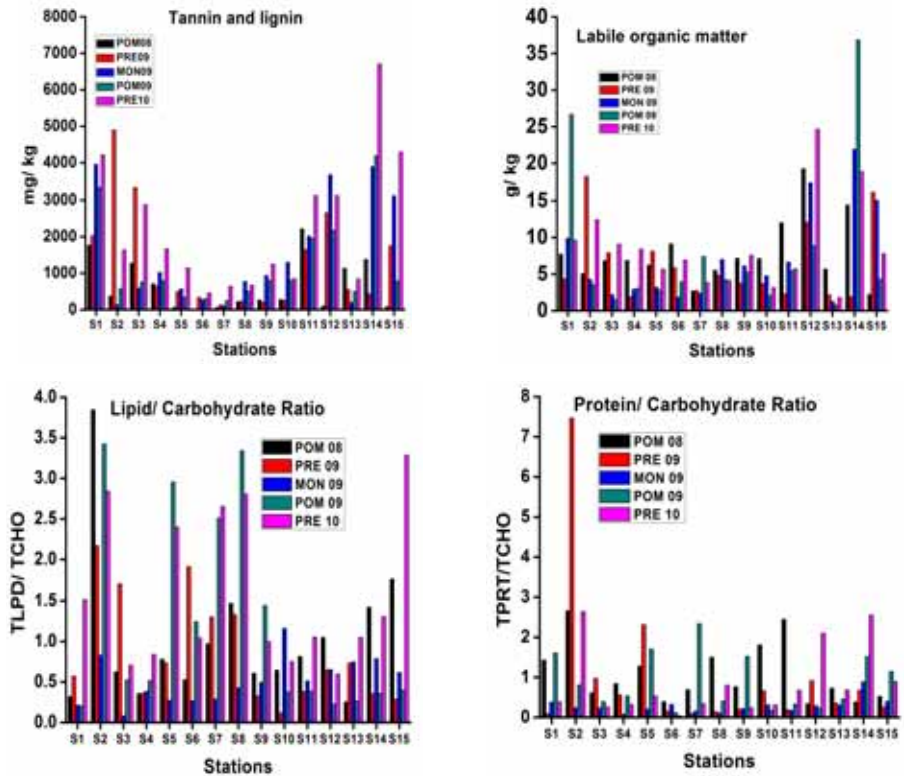

Figure 3.12 Spatial and seasonal variation of biochemical components and sediments

Total lipids (LPD)

During POM 08, lipid in sediments ranged from 724.3 to 8451 mg/kg with an average of 2451±2291mg/kg. In PRE 09, lipid content varied from 240 to 3711mg/kg and recorded an average content of 1814 ±1332mg/kg. While during MON 09, it was observed that the concentration ranged from 132.1 to 6456 mg/kg and the estimated average content was 2037±2004mg/kg. However, POM 09 revealed a minimum of 115.29 and maximum of 4587mg/kg with an average of 1699±1213 mg/kg. The content of lipid in sediments during PRE10 exhibited values between 688.7 and 5450mg/kg (average: 3355±1407mg/kg).

Total organic matter (TOM)

During POM 08, total organic matter in sediments ranged from 1.52 to 8.84 % and recorded an average content of 4.46±2.56%. In PRE 09, TOM varied from 0.80 to 10.39% and recorded average was 4.34±3.43%. The concentration of TOM during MON 09 ranged from 0.28 to 11.01 % and estimated average was found to be 4.56±3.49%. While in POM 09, value varied from 0.62 to 9.95 % and the observed average content was 4.56±3.17%. The concentration of TOM during PRE 10, ranged between 1.05 and 8.59% (average: 4.09±2.67%). Spatiotemporal variation in TOM content is furnished in figure 3.8.

Labile organic matter (LOM)

In the present study, POM 08 recorded LOM content ranging from 2215 to 19262mg/kg and recorded an average content of 7861±4426mg/kg (table 3.5). In PRE 09, LOM varied from 1916 to 18205mg/kg and recorded average was 6396±5222mg/kg. The concentration of LOM during MON 09 ranged from 1268 to 21910 mg/kg and estimated average was found to be 7111±6272mg/kg. While in POM 09, its content varied from 746 to 36847 mg/kg and estimated average was 7779±1014mg/kg. The content of LOM during PRE 10, ranged between 1792 and 2466 mg/kg (average: 8631±6092mg/kg).

Lipid/Carbohydrate ratio

During POM 08, lipid/carbohydrate ratio in sediments ranged from 0.25 to 3.85 and the recorded average was 1.02±0.89. Meanwhile during PRE09, lipid/carbohydrate proportion varied from 0.12 to 2.16 (average: 0.86±0.65). But during MON 09 the estimated ratio ranged from 0.08 to 1.16 with an average of 0.51±0.28. However POM 09 recorded a minimum

of 0.20 and maximum of 3.42 (average: 1.21±1.21). In the case of PRE 10, the ratio ranged from 0.59 to 3.28 and exhibited an average of 1.58±0.92.

Protein/ Carbohydrate ratio

Spatiotemporal variation of PRT/CHO ratio is depicted in figure 3.12. During POM 09, PRT/TCHO ratio in sediments ranged from 0.34 to 2.66 and recorded an average value of 1.09±0.74. In PRE 09, PRT/CHO varied from 0.09 to 7.46 and estimated average was found to be 1±1.87. MON 09 exhibited PRT/CHO ratio ranging from 0.07 to 0.88 with an average of 0.28±0.19. While during POM 09, its value ranged 0.11 to 2.33 and estimated average value was 0.88±0.69. PRE 10 showed a variation from 0.04 to 2.63 (average: 0.85±0.85).

Chlorophyll a

The estimated concentration of chlorophyll a during POM 08 ranged from 0.46 to 13.6 µg/kg with an average of 6.7 ±4.2µg/kg (table 3.5). In PRE 09, it recorded a variation from 1.42 to 18.49 µg/kg and recorded an average content of 8 ±6.1µg/kg. While during MON 09, it was observed that the content of chl a ranged between 0.36 and 16.43µg/kg and the estimated average content was found to be 6.2±4.5µg/kg. However, POM 09 revealed a minimum of 0.59 µg/kg and maximum of 16.89 µg/kg with an average of 7.4±4.9 µg/kg. The content of chl a in sediments during PRE 10 exhibited values between 0.74 and 16.54µg/kg (average: 9.1±4.6µg/kg).

Chlorophyll b

POM 08 exhibited chlorophyll b content ranging from 0.69 to 7.07 µg/kg with an average of 3.8 ±2.1µg/kg. In PRE 09, it varied from 0.87 to 11.73µg/kg and recorded an average content of 4.1±2.9µg/kg. While during

MON 09, it was observed that the concentration ranged from 0.24 to 7.0µg/kg and the estimated average content was 2.7±1.9µg/kg. However, POM 09 revealed a minimum of 0.75 and maximum of 7.39 with an average of 3.6±2.0µg/kg. The content of chl b in sediments during PRE10 exhibited values between 0.54 and 15.83µg/kg (average: 4.7±3.4µg/kg).

Chlorophyll c

Chlorophyll c exhibited concentration ranging from 0.66 to 8.4 µg/kg with an average of 4.4±2.2µg/kg during POM 08. In PRE 09, it varied from 1.03 to14.59 µg/kg and recorded an average content of 4.86±3.47µg/kg. While during MON 09, it was observed that the concentration ranged from 0.23 to 6.91µg/kg and the estimated average content was 3.15±1.83µg/kg. However, POM 09 recorded a minimum chl c content of 0.88 µg/kg and a maximum of 7.09µg/kg with an average of 4.01±1.93 µg/kg. The content of chl c in sediments during PRE10 exhibited values between 0.51 and 26.19µg/kg (average: 5.91±5.86µg/kg).

Tannin and Lignin

Spatiotemporal varion in concentration of tannin and lignin in sediments is represented in figure (3.12). In the present investigation, POM 08 exhibited tannin and lignin content ranging between 7.18 and 2215 mg/kg with an average of 659±714mg/kg (table 3.5). In PRE 09, it varied from 126 to 4898mg/kg and recorded an average content of 1303±1409mg/kg. While during MON 09, it was observed that the concentration ranged from 113.5 to 3957mg/kg and the estimated average content was 1503±1443mg/kg. However, POM 09 revealed a minimum of 244.81 mg/kg and maximum of 4193 mg/kg with an average of 1202±1185mg/kg. Concentration of tannin and lignin in sediments during

PRE10 exhibited values between 453.81 and 6706mg/kg (average: 2229±1794mg/kg).

Discussion

Rainfall is the most important cyclic phenomenon in tropical countries as it brings important changes in the hydrographical characteristics of the marine and estuarine environments. During the present study, the maximum rainfall was recorded during south west monsoon. In the present study, the peak values of rainfall were recorded during MON 09. The rainfall in India is largely influenced by two monsoons viz., southwest monsoon on the west coast, northern and northeastern India and by the northeast monsoon on the southeast coast (Perumal, 1993).

Generally, temperature of surface waters is influenced by the intensity of incident solar radiation, evaporation, freshwater influx and cooling and mix up with ebb and flow from adjoining neritic waters. The surface and bottom water temperature (average) during post monsoon was lower because of strong land sea breeze and underwater currents and the recorded high value during premonsoon could be attributed to higher insolation rate of solar radiation (Karuppasamy and Perumal, 2000; Senthilkumar et al., 2002; Santhanam and Perumal, 2003). In the present investigation, there was no spatial variation ($p>0.05$) observed in temperature which could be due to the lack of viable intensity of prevailing streams and the resulting mixing of water (Reddi et al., 1993). Statistical analysis (ANOVA) showed that there is no spatial variation and therefore be concluded that stations are almost similar temperature, but with high seasonal variation ($p<0.01$). Present study recorded the minimum temperature at S9 (MON 09) and maximum at S5 (PRE 09).

The tidal mixing and estuarine circulation are crucial factors influencing the hydrographic status of an estuary which in turn affect the nutrient distribution and productivity. Cochin backwater system is characterized by an ox-bow shape, running parallel to Arabian Sea (Soman, 1997). Due to its peculiar topography, the circulation patterns in the northern and southern arms of the CBW are found to be different (Ramamirtham and Muthusamy, 1986).The higher freshwater flow during summer monsoon suppresses the tidal characteristics and increases stratification in the lower estuary (Qasim and Gopinathan, 1969). Tides at Cochin estuarine system are of a mixed semi-diurnal type, with the maximum spring tide range of about 1m (Srinivas, 1999), resulting in incomplete flushing. Hydrobiological studies of the estuary (Menon *et al*., 2000) showed that the high flushing during monsoon completely transforms the estuary into a freshwater habitat.

Wide fluctuations in the values of transparency (figure 3.4) might be due to discharge of water due to floating sediments carried by the river from catchment areas. Dredging operations to maintain the average depth of ship channel, Cochin harbour area, Cochin Shipyard and Vallarpadom Container Terminal region, generates huge loads of suspended sediments which affect the transparency of water column. It is evident that heavy rainfall and intense cloud cover prevailing in the monsoon season reduces solar insolation and the high input of suspended sediments makes the estuary more turbid (Renjith et al., 2012). However, during the post-monsoon period, the excess nutrients carried to the estuarine system through the land runoff, increased solar radiation and reduction in turbidity result in the development of an ideal environment for high primary production. In the present investigation, the estimated light attenuation

coefficient was higher during MON 09, a similar observation reported by Madhu et al., 2009 and thereby the light limitation significantly reduces the primary production during this particular season. Generally, higher attenuation values are expected in the monsoon months especially during flood conditions due to likely increase in turbidity of the water and low intensity of solar radiation due to the intense mixing of water having heavy loads of suspended particulate matter (Sarala Devi, 1989). Low values of extinction coefficients were recorded during premonsoon months, which indicated a higher transparency.

Significant spatial and temporal variability of physico-chemical characteristics and productivity patterns are among the important characteristics of estuaries (Renjith et al., 2012). Physico-chemical parameters like nutrient concentrations, algal chlorophyll, water transparency (Carlson, 1977; Kratzer and Brezonik, 1981) and primary production measurements (Nixon, 1995) have often been employed to assess trophic status of water.

In the present investigation, the values of pH in both surface and bottom waters remained slightly alkaline at all the stations. Recorded pH during POM 10 was maximum at S9 (surface water), but in maximum was recorded at S8 (bottom water) during PRE 09. Generally, fluctuations in pH values during different seasons of the year is attributed to factors like removal of CO_2 by photosynthesis through bicarbonate degradation, dilution of seawater by freshwater influx, low primary productivity, reduction of salinity and temperature and decomposition of organic materials (Karuppasamy and Perumal, 2000; Rajasegar, 2003). Higher values for pH were recorded during summer seasons, which might be due to the influence of seawater ingression, increased photosynthetic activity

(Subramanian and Mahadevan, 1999). The statistical analysis also revealed that salinity showed highly significant negative correlation with rainfall. In the present study, pH (bottom layers) showed highly significant positive correlation with salinity and alkalinity which might be attributed to the fact that rise in pH values associated with increasing salinity and alkalinity, is a general phenomenon observed in aquatic systems.

The maximum DO content was recorded at FACT- Kalamassery (S15) (surface) and at Murinjapuzha –Brahmamangalam(S3) (bottom) during PRE 10. Statistical analysis (ANOVA) showed that there is much seasonal and spatial variation in DO (both surface and bottom layers). It is well known that the temperature and salinity affect the dissolution of oxygen (Vijayakumar et al., 2000). In the present investigation, higher content for dissolved oxygen was recorded during monsoon, which could be due to the cumulative effect of higher wind velocity joined with heavy rainfall and the resultant freshwater mixing (Das et al., 1997). Mitra et al., (1990) mainly attributed seasonal variation of DO to freshwater flow and terrigenous impact of sediments. Further, significant inverse relationship between rainfall and nutrients indicated that freshwater flow constituted the main source of the nutrients in the estuary. In surface waters, the negative correlation of DO with salinity implied the general fact that solubility of oxygen decreases with increase in salinity.

Phytoplankton photosynthesis drives many biogeochemical and ecological processes in lakes, estuaries, and the ocean. Dynamic changes in pH, trace metal speciation, and concentrations of dissolved gases (oxygen and carbon dioxide), inorganic nutrients (nitrate, phosphate, silicate), and organic compounds (amino acids, organosulfur compounds) are all closely associated with fluctuations in phytoplankton photosynthesis. Trophic

linkages also exist, between the phytoplankton as primary producers and populations of consumer organisms including bacteria, zooplankton, benthic invertebrates, and fish.

Biochemical oxygen demand depends on temperature, extent of biochemical activities, concentration of organic matter and such other related factors. Maximum value of BOD was observed in pre monsoon period due to the restricted flow of oxygenated water from upper reaches of the contributing river (Renjith et al., 2012). The higher biological production coupled with sinking of organic matter also leads to a high oxygen demand in the water column (Martin et al., 2010). Rapid industrialisation and urbanization in the around Cochin area has resulted in a daily discharge of about 104 million litres of untreated effluents and 260 m^3 of raw sewage into the backwater system (Qasim 2003; Balachandran et al., 2005). Waste disposal from aquaculture fields and agricultural fields have worsened the organic pollution in this unique aquatic system. The combined effects of all these factors might be contributed to the increased BOD levels in the study area.

Both surface and bottom waters exhibited spatial and seasonal variation ($p < 0.01$) for salinity. In the present investigation, no vertical stratification was observed and fresh water conditions were prevalent during the monsoon season. However, stratification was observed during the post-monsoon season. Higher values for salinity noticed during post monsoon season (figure 3.4) could be due to increased rate of evaporation and the neritic water dominance. The salinity acts as a limiting factor in the distribution of living organisms, and its variation caused by dilution and evaporation is most likely to influence the fauna in the intertidal zone (Gibson, 1982). Generally, changes in the salinity in the brackish water

habitats like backwaters might be due to the influx of freshwater from land run off, caused by monsoon or by tidal variations. In the study area, POM 08 recorded higher values which could be attributed due to the higher tidal inflow of saline water. During the monsoon season, the rainfall and the freshwater inflow from the land in turn moderately reduced the salinity (Govindasamy et al., 2000; Gowda et al., 2001; Rajasegar, 2003; Qasim, 2003). It was observed that during the present investigation, salinity displayed highly significant negative correlation with DO indicating the fact that higher salinity inhibits the dissolution of atmospheric oxygen.

Analysis of variance was carried out to compare the free CO_2 in the surface and bottom water which revealed no significant difference among the stations. In the present investigation concentration of CO_2 found to exhibit highly significant seasonal variation ($p<0.01$). Estuaries have been regarded as a significant source of CO_2 to the atmosphere (Frankignoulle et al., 1998). This CO_2 is produced in high concentrations in estuarine regions which were known to be heterotrophic systems, where organic carbon transported by rivers is partly mineralized (Gattuso et al., 1998).

Nutrient levels are important determinants of biodiversity, influencing the processes of competition and community structure in the water bodies. In the pelagic waters, concentration levels of inorganic nutrients such as nitrate, phosphate and silicate in the water dictate population growth of planktonic primary producers. Rates or pathways through which exogenous nutrients are converted into algal biomass is different among estuaries (Cloern, 2001). Eutrophication caused by excess supply of nutrients from industrial and domestic activities can influence coastal and estuarine waters (Barmawidjaja et al., 1995; Tsujimoto et al., 2006). Increased input of nutrient to the CBW is not only from the rivers

but also contributed by increased industrial and domestic activities (Jyothibabu et al., 2006). Monsoon rain, after the dry summer period (January to May) washes the adjacent land area and drain nutrient enriched waters to CBW, making the system highly productive (Qasim,2003; Madhu et al., 2007).

Nutrients are generally considered to be the limiting factors for phytoplankton productivity. The nutrient content of estuaries is determined by their concentration in the riverine and coastal water sources. Generally nitrate, nitrite, phosphate and silicate are regarded as essential nutrients for plankton growth which affects the survival and population fluctuation of other fauna and flora in the food chain (Pramodbabu, 2007). The changes and seasonal cycles of these nutrients control most of the biological activities in estuarine systems. The nitrogen as nitrate and phosphorus as phosphate greatly augment the primary productivity and both are essential for the survival of primary producers, yet they subsist in very small concentration in the surrounding medium. Very low concentration of silicon present in the water can limit phytoplankton production due to the suppression of metabolic activities of the cell. Silicon represents a vital nutrient for the skeletal growth of diatoms (Pramodbabu, 2007).

In the present investigation, average values of ammonia was found to be higher during premonsoon season (figure 3.5) and this may be partly due to the death and subsequent decomposition of phytoplankton and also might be the excretion of ammonia by planktonic organisms (Segar and Hariharan, 1989; Ananthan, 1994; Rajasegar, 1998). Some stations exhibited higher values that may be due to industrial effluents and terrestrial input. Ammonia displayed a non-uniform distribution throughout

the entire study period which indicated an exogenic input in the estuary (Renjith et al., 2011; Renjith et al., 2012).

The recorded maximum for nitrate content (37.63µmol/L) during monsoon season (figure 3.5) could be mainly due to the organic materials received from the catchment area during ebb tide and similar results were also recorded by Das et al., 1997. Besides, the increased nitrate level was due to fresh water inflow, organic decomposition and terrestrial run-off during the monsoon season and previous literature by Karuppasamy and Perumal, (2000) supports these facts. Another possible way of nitrates entry is through oxidation of ammonia form of nitrogen to nitrite formation (Rajasegar, 2003). The minimum concentration of (8µmol/L) was recorded during post monsoon period may be due to its utilization by phytoplankton as evidenced by high photosynthetic activity apart from the neritic water dominance, which contained negligible amount of nitrate (Rajashree Gouda and Panigrahy, 1995; Das et al., 1997; Govindasamy et al., 2000). In the present investigation, the increased in nitrate content observed during the monsoon season, higher content in the low saline stations and the significant negative correlation with salinity, indicated the riverine input (Renjith et al., 2012). Moreover, nitrate in water column showed highly significant positive correlation with DO which inferred the fact that oxygenated condition favoured the formation of nitrate.

During the present investigation the nitrite content was lower during monsoon season (figure 3.5). Nitrite exhibited its maximum at S14 (POM 08) and S6 (PRE 10) in surface and bottom waters respectively. Average nitrite content in surface and bottom water was also found to be higher during the pre monsoon and which could be attributed due to the variation in phytoplankton, excretion and oxidation of ammonia and reduction of

nitrite (Kannan and Kannan, 1996). The lower contents of nitrite during the premonsoon season were due to less freshwater input, higher salinity, pH and also uptake by phytoplankton. The similar situation has already been reported (Edwards and Ayyakannu, 1991; Mathevan, 1994). Highly significant seasonal variation (p value<0.01) was recorded for this parameter in the case both surface and bottom waters.

Both surface and bottom waters exhibited lower content for phosphorous during PRE 10 (Figure 3.14), which could be attributed to the limited flow of freshwater, high salinity and utilization of phosphate by phytoplankton (Senthilkumar, et al., 2002; Rajasegar, 2003). PRE 09 exhibited higher phosphate concentration due to high rainfall and freshwater inflow compared to PRE 10. The addition of super phosphates applied in the agricultural fields as fertilizers and alkyl phosphates used in households as detergents can be other sources of inorganic phosphates during the season (Das et al., 1997; Senthil Kumar et al., 2002). Analysis of variance applied to test the significance of difference between stations showed that phosphate concentration differ spatially in surface waters ($p<0.05$) compared to bottom waters ($p>0.05$). The variation may be due to the processes like adsorption and desorption of phosphates and buffering action of sediment under varying environmental conditions (Rajasegar, 2003). The higher phosphate content in the water column could be attributed to regeneration and release of total phosphorus from sediment into the water column by turbulence mixing (Chandran and Ramamoorthy, 1984). Phosphate exhibited highly significant seasonal variation ($p<0.01$). In the present study, dissolved inorganic phosphate displayed significant positive correlation with salinity indicating the internal loading (Renjith et al., 2012).

The distribution pattern of salinity and silicate and their interrelationship in Cochin backwater system was investigated by (Anirudhan et al., 1987) and pointed out the fact that construction of Thanneermukkom bund had led to the stagnation of water resulting in the large changes in the hydrography. In the present study, both surface and bottom waters exhibited higher silicate content during POM 08 and POM 10 (Figure 3.15). The maximum content was recorded at Aroor-Kumbalam (S6) (surface) during POM 09 and Eloor (S13) (bottom) during POM 09. Highly significant seasonal ($p<0.01$) variation was noticed for silicate in the surface waters of the study area. However, in bottom waters, the significant spatial ($p<0.05$) and seasonal ($p<0.01$) variations were observed. Silicate exhibited significant negative correlation with salinity, suggesting its input through land runoff (Renjith et al., 2012).

Primary production can be limited by Fe availability in coastal environments (Kirchman et al., 2000; Bruland et al., 2001). Dissolved Fe in aquatic systems can exist in two different oxidation states [Fe (II) and Fe (III)]. The Fe (III) is the thermodynamically stable form in oxygenated waters and has a very low solubility in high saline water (Liu and Millero, 2002). Fe (III) becomes rapidly hydrolyzed into various Fe(III) oxyhydroxides. The low solubility of Fe oxyhydroxides and the tendency to form colloids which can contribute to the scarcity of directly bioavailable Fe species in the marine environment (Wen et al., 1999). Dissolved Fe (III) occurs for a major part as complexes (Fe (III)) with strong organic ligands (Waite, 2001). The majority of dissolved Fe in river water exists as small colloid particles (Wen et al., 1999). Flocculation of these colloids, upon mixing of fresh river water with seawater during estuarine mixing, causes a massive removal of the freshly formed particulate Fe (Sholkovitz, 1978).

Riverine dissolved iron, comprises mostly colloidal iron oxy-hydroxides closely associated with natural organic matter (Nowostawska, 2008). Organic complexation is an important factor in the biogeochemistry of Fe in estuarine waters, as it maintains iron in the dissolved phase at high salinities beyond the flocculation zone. The dissolved phase will be flushed from the estuary while the non-organically complexed fraction tends to aggregate and adsorb to particles, thereby exhibiting longer residence time (Morris et al., 1986). Organically complexed iron of estuarine systems can act as a source of dissolved iron for coastal waters (Powell and Wilson-Finelli, 2003).

Texture analysis of sediments revealed that during MON 09, most of the stations exhibited the dominance of mud (silt + clay) except S13. During POM 10 majority of the stations exhibited muddy-sand /silty-sand character, but S3 and S4 displayed sandy nature. Almost all the stations showed the dominance of mud, while S2, S4, S13 and S14 exhibited sandy nature during POM 09. Sand dominated sediments were observed at S3, S4, S5, S11, S13, S14, and S15 during PRE 09. The occurrence of mud as the major grain size fraction at S6, S7, S8, S9, S10 and S12 could also be noticed. The stations S1, S2, S6, S8, S12 and S14 were muddy in nature and others were dominated by sand during PRE 10. Determination of textural components in aquatic sediments is an essential requirement for the better understanding of fluvial process. The content of textural components and their relative proportions have a strong bearing in the physico-chemical characteristics of aquatic environments. It is an important abiotic measure determining the living condition / environment of aquatic flora and fauna.

A large part of the carbon flux between terrestrial and marine systems is mediated by estuaries (Holligan and Reiners, 1992). Terrestrial

carbon enters the estuary mainly through freshwater tidal reaches. Significant fraction of the particulate and dissolved organic matter becomes associated with sediment particles to form large macro-aggregates called estuarine flocs (Eisma, 1993). The high sinking rates due to the specific hydrodynamic conditions of estuaries, these flocs accumulate in turbidity maxima situated in the upstream estuarine reaches (Largier, 1993). Because of the increased residence time of particles in the turbidity maxima, most of the terrestrial organic matter entering the estuary is respired in the freshwater tidal to brackish estuarine zones (Frankignoulle et al., 1998). Inspite of the higher productivity, the transfer coefficient from primary to secondary level in the Cochin backwater system is only 7% and the excess organic matter may be transported to the coastal waters or sink within the estuary (Madhupradhap et al., 1980; Jyothibabu et al., 2006).

Higher concentration for organic carbon reported at Cheranellur (S12) during MON 09 (figure 3.7) could be attributed to anthropogenic input of organic matter derived from land runoff. Lower contents for TOC recorded at Eloor (S13) might be attributed to the dilution effects associated with high river discharge from River Periyar. Analysis of variance (ANOVA) revealed highly significant spatial variation ($p<0.01$). Organic carbon constitutes an integral part of aquatic sediments. The increased attention in the determination of organic carbon in the sediments of various aquatic environments is due to its significance in assessing the biological, chemical and geological process operating in these environments. Organic carbon in sediments may be derived from autochthonus or allochthonus processes. Sedimentation followed by diagenetic decomposition of organic carbon can alter the Eh-pH conditions of aquatic environments. Further, the organic carbon in the form of organic matter provides the main energy

source for the heterotrophic organisms living in aquatic environments. The organic carbon distribution in an aquatic environment is controlled mainly by the textural attributes of sediments. An understanding of the distribution of organic carbon and its bearing on the physico-chemical and biological parameters is very much essential for assessing the extent of nutrient input and/or pollution load in aquatic systems. In the present investigation, the strong association (table 3.6) between organic matter with clay and silt speculated to be a result of sorption of organic matter to mineral surfaces. The fact that much of organic matter is not easily removed from the mineral matrix has major ramifications for the role of sorptive preservation of organic matter in sedimentary environments. One reason for such stability is that organic matter may be lodged in small mesopore-sized spaces which are too small for access by microbial enzymes (Mayer, 1994).

Total organic carbon/ total sulphur (TOC/ TS) ratio provides a qualitative indication of the redox status of the environment of deposition, when TS concentrations are high (Raiswell et al., 1987). TOC/ TS ratios > 5 are considered as oxic sediment with oxygenated bottom water, TOC/ TS = 1.5-5 indicates sediments deposited under periodic anoxia and TOC/ TS < 1.5 represents anoxic sediment with anoxic water. The average TOC/ TS values in the study region can be included in the second category (periodic anoxia) suggesting that the sediments undergo sulphate reduction below an oxygenated water column (Hedges and Keil, 1995).

Stoichiometric ratios of nutrients are utilized to determine the origin and transformation of organic matter (Yamamuro, 2000). According to Redfield, (1958), C/ P ratio for algal material is 7. Hecky et al., (1993) indicated that wide range of C/ P and N/ P ratios in aquatic sediments can still be considered to follow Redfield ratio (C/ P= 28 to 56 and N/ P=4 to

9). The lower values for this ratio indicated enrichment of phosphorous in sediments of the estuarine system. The observed N/P ratio in estuarine sediments revealed considerable variations among stations. The lower N/P ratios also suggest that there might be higher benthic nitrogen recycling, and denitrification, and the benthic release of nitrogen could play a role in sustaining the productivity of the system (Renjith et al., 2010). The C/P ratio recorded maximum in the seasons POM 09 and PRE 10 at same station S2, due to the higher organic carbon content derived from domestic sewage. The N/P recorded maximum at S2 (POM 09).

Anthropogenic activities like industrialization, urbanization and agricultural runoff have resulted in tremendous ecological stress on aquatic ecosystems. Most of estuarine sediments around the world possess increased levels of nutrients, and other ecologically harmful chemical compounds. The problem is further complicated by the fact that most of these pollutants tend to adhere on suspended organic and inorganic particles which ultimately deposited in aquatic sediments. These contaminants may continuously released from the sediments by diffusion or resuspension. Sediment is the source of nutrient for macrophytes (Jin et al., 2006). Release from the sediment-water interface has been suggested as the main pathway for nutrient recycling (Sanchez-Carrillo et al., 2006). Nitrogen occurs in sediments in various forms like nitrate, nitrite and ammonia and a range of organic nitrogen compounds, like amino acids, urea and humic substances. Nitrate is the most stable form of nitrogen under oxic conditions.

In the present investigation, concentration of ammonia was much lower in sediments, and could be explained by that the processes like denitrification and nitrogen fixation can determine available nutrient ratios (Mc Carthy et al.,

2007). Its maximum content was recorded at S15 (POM 08).Besides, dissimilatory nitrate reduction to ammonium is also important, relative to denitrification. The anoxic conditions are more favourable for maintaining high NH_3/NH_4^+ levels, mainly because the conversion of NH_4^+ to nitrate by nitrification remains low because of the lack of dissolved oxygen under these conditions. Nitrification coupled with denitrification converts biologically available N forms (NH^{4+} and NO_3^-) to molecular nitrogen gas and may reduce effects of excessive N inputs and eutrophication. Release of ammonium from sediments was reported during periods of hypoxia and anoxia (Berman et al., 1999). The fluxes of ammonia from benthic recycling and from the river discharge could be of the same order of magnitude in monsoon as well as non monsoon seasons (Padma, 2005).

Nitrate for coupled denitrification derives from organic matter mineralization to NH_4^+ followed by nitrification. Dissimilatory nitrate reduction to ammonium is an alternative pathway for nitrate in sediments (An and Gardner, 2002). The relative partitioning between nitrate reduction pathways is also regarded as an important mechanism, since denitrification removes fixed N from the system while dissimilatory nitrate reduction returns it as bioavailable ammonium. The higher nitrogen and phosphorus concentrations of sedimentary nitrate-N in the present study pointed to higher rate of nitrification and less denitrification. Nitrification, the conversion of ammonia (NH_3) to nitrate (NO_3^-) via nitrite (NO_2^-), is essential to the function of the nitrogen cycle in aquatic environments (Urakawa et al., 2006). The very low concentrations of nitrite-N in the sediment revealed the fact that the nitrite-nitrogen is intermediate in oxidation state between ammonia and nitrate, and as such it can appear as a transient species in both the oxidation of ammonia and the reduction of

nitrate. Mixing with sea water was found to exert a negligible effect on the concentration of nitrite-N in the sediment. Being very low values, it could be assumed that the nitrite-N is more or less uniformly distributed in the sediments of the study area and thus it ruled out any conditions for the existence of anoxic basins in any of the sampling sites.

Analysis of variance revealed that only spatial variation was highly significant ($p<0.01$) in the case of nitrate. In the present study, NO_3^- was higher during POM 08 and POM 09 and recorded lower concentration during PRE 09 and PRE 10. The higher nitrate-N concentrations are related to more intense mixing of the super lying water column due to rain, land run off and high river discharges. The higher values were particularly important where there was influence on sediment from agriculture, industries and waste water and also physical degradation of the land area. The lower values in the sediments could be attributed to the sandy nature of the sediments. The enriched levels of nitrogen compounds in the backwaters could be attributed to the discharge of industrial, domestic, and agricultural wastes (Saraladevi et al., 1991; Qasim, 2003).

Fractionation is the method used to characterize phosphorus in aquatic sediments and it separates phosphorus into different forms based on solubility and reactivity against various reagents. Sequential chemical extraction techniques have been a useful tool to examine these processes (Ruttenberg, 1992; Jensen and Thamdrup, 1993), since the analysis of total sediment phosphorus does not represent an accurate measurement of phosphorus exchangeability and bioavailability for algal growth. In the present study, fractionation was employed to quantify different fractions of phosphorus in the estuarine sediments in order to assess the processes leading to the fractional distribution of phosphorus, its bioavailability and influence on the trophic

status. Bioavailability and cycling of phosphorus in estuaries depend upon phosphorus fractionation (Andrieux-Loyer and Aminot, 2001). Conditions like salinity, pH or redox potential present in estuarine systems determines the relative importance of each fraction of P (Lebo, 1991; Paludan and Morris, 1999). Phosphorous in sediments can be found in association with iron, aluminium and calcium oxides or adsorbed on the mineral surface and organic materials. In order to eliminate the disadvantages such as uncertainity in the bioavailable and the nonspecific nature of the extraction solutions, an extraction scheme using chelating agents was developed by Golterman, (1996). This procedure is useful for the extraction of inorganic phosphorus pools with lesser modifications of the organic pool.

Iron-bound IP fraction was found to be the main phosphorous pool in the estuary, and exhibited a seasonal maximum accounting for 28.66% (S6, POM 08), 48.83% (S14, PRE 09) 60.62% (S5, MON 09), 74.80% (S7, POM 09) and 69.37% (S4, PRE 10) of the total phosphorus. Iron- and calcium-bound inorganic fractions and acid soluble organic fractions of phosphorus are generally considered to be bioavailable (Diaz-Espejo et al., 1999). Contribution of bioavailable fraction to total P was in the range: 29.45±14.77% (POM 08); 68.27±13.4% (PRE 09); 70.68±23.8% (MON 09); 97.24±3.85±3.85% (POM 09); 89.50±6.19% (PRE 10). Present study revealed that the bulk of the total phosphorus is bioavailable; the estuarine sediments have the potential to act as source of phosphorus to the overlying waters (Joseph et al., 2010). The Fe bound P exhibited highly significant positive correlation with clay, silt, TOC, TN, TS, chlorophyll pigments and negative correlation with sand pointed towards influence of granulometry and diagenetic processes controlling its distribution. The variations in concentration of different P fractions are depicted in figure 3.23.

Correlation analysis confirmed the significant interrelations among the bioavailable fractions. In estuarine sediments, the calcium bound phosphorous exhibited significant positive correlation (table 3.6) with total carbon, organic carbon and acid soluble organic phosphorous. The Ca bound P exhibited significant positive correlation with clay, silt, TOC, TS, Chl b and significant negative correlation with sand inferred the fact that texture and granulometry influences the distribution of calcium bound phosphate. Significant positive correlation with sulphur, the redox indicator also suggested that there is preferential accumulation of Ca-IP when the system is highly reducing.

Fe-IP displayed highly significant positive correlations with other two bioavailable fractions (Ca-IP and ASOP) and Ca-IP exhibited highly significant positive correlations with ASOP. The P-fractions available for biological uptake are all well correlated indicating a common biogeochemical balance. In the present investigation the acid soluble P exhibited significant high positive correlation with clay and TOC, since the components in this fraction are organic and clay provides adsorption sites for these organic compounds.

The main inorganic forms of P are the fraction associated with Al, Fe and Mn oxides and hydroxides. Phosphorus and iron are usually strongly associated in sediments, P being adsorbed onto iron compounds with the formation of iron phosphate complexes. The amount of FeOOH is therefore one of the factors controlling P release from sediment. Fe-IP, which is exchangeable between the particulate and dissolved phases through sorption processes, was the major fraction in estuarine sediments

(majority of the stations). Salinity plays a role in the seasonal variations of P fractions as it controls the flocculation and sedimentation mechanisms in estuarine environments, changing the availability of elements (Kautsky, 1998). During the monsoon season, when the system changes to a freshwater condition, Ca-IP is found to be lower. It might be due to the lower availability of solid calcium carbonates, which is governed by salinity and pH (Huanxin et al., 1994; Zwolsman, 1994). In estuarine sediments, Ca-IP, referring to the fraction that is fixed in sediments and may be lost into deep sediments through the burial process, which exhibited significant positive correlation with total carbon, organic carbon and total nitrogen (table 3.6). The observed variation for Ca-IP concentration was from 0.38% (S10, POM 08) to 37.91%. Carbonate-adsorbed P has been identified as an important and potentially dominant phase of P in shallow-water tropical carbonate-rich sediments, due to the high adsorption capacity of carbonates (Millero et al., 2001). In the present investigation, the higher concentration of calcium-bound P in the estuarine sediments might be interpreted by the favourable accumulation of calcium carbonate under higher salinity and pH conditions (Huanxin et al., 1994). The increase in Ca-IP at some stations estuary (pre and post-monsoon) might be due to increase in salinity. Similar trend is reported in marine sediments presumably by the accumulation of calcium under high salinity, which favours apatite formation (Ryden et al., 1997). Silva and Mozeto, (1997) also suggested that phosphorus combine with calcium under high salinity and this process acts as a principal mechanism for retention of phosphorous.

The maximum contribution of ASOP to total P during each season was found to be 16.3% (S7, POM 08), 16.56% (S11, PRE09), 18.84 % (S10 MON 09), 26.17% (S3, POM09) and 17.48% (S14, PRE10). Acid soluble organic phosphorous varied from 0.47% (S13, MON 09) to 26.17% (S3, POM 09). ASOP includes apatite bound phosphate and biochemical components such as nucleic acids, lipids and sugars that bound to phosphate (De Groot, 1990). ASOP had highly significant positive correlation with total sulphur in mangrove sediments indicated that highly reducing environment is favourable for retention of ASOP in sediments similar to Ca-IP.

The concentration of Alk-OP contributed its maximum towards total phosphorous pool at S13 (94.46%; MON 09). Alk-OP generally constitutes humic phosphate and phytate phosphate (Golterman, 2001). Phosphorus associated with humic acids has been considered either to be an integral part of humic acids or as a phosphate metal/organic matter complex (Stevens and Stewart, 1982). During the study, the alk-P exhibited significant negative correlation with silt, pointed towards the allochthonous origin of this fraction.

Residual organic-P was the smallest fraction estimated in sediments collected from estuarine stations. The RP varied from 0.01% (S14, PRE10; S12, POM 08) to 94.46% (S13, MON 09). Total phosphorus content in the estuarine sediments varied from 199.88 mg/Kg (S3, POM 10) to 12900.59 mg/kg (S12, POM 08). Organic phosphorus is a complex fraction, the exact nature of which is not precisely known (Reitzel et al., 2007). As a result of diagenetic reorganization of phosphorus within sediments, organic

phosphorus concentrations usually decrease with time as it is ultimately transformed to authigenic phosphorus during diagenesis (Ruttenberg and Berner, 1993; Andersen et al., 2001). The lower content of this fraction in sediments of estuarine stations might be attributed to diagenesis. In the present study, strong positive correlation of residual phosphorous with sulphur (table 3.6) confirmed the occurrence of diagenic processes. Degradation of organic P compounds also releases phosphate (PO_4-P), making it available to bacteria and algae. As a result of the diagenetic reorganization of P within sediments, organic phosphorous concentrations usually decrease with time as it is ultimately transformed to bioavailable forms. Bacteria are generally considered to be the catalysts that accelerate the solubilization of P (Gatcher and Meyer, 1993) and the processes of anoxic mineralization of phytate (Golterman et al., 1998) could release organic P buried during monsoon season. Generally, organic bound phosphorus accounted for 6 to 19% of total in coastal sediments (Hirata, 1985). Also organic phosphorus mineralization is high under anaerobic condition than aerobic conditions (Bridgam et al., 1998). Highly negative redox potential of sediments of the study area resulted in higher mineralization and subsequently lower concentration of organic phosphorus. Res-P exhibited correlation of residual P with TOC and total sulphur pointed towards diagenesis since sulphur is the redox indicator.

* Significant at 0.05 level, ** Significant at 0.01 level

The assessment of the quantity and quality of organic matter, whether labile or refractory, is a prerequisite for explaining diagenetic processes. Biochemical composition of sedimentary organic matter has been used to gather information on the origin and parameters controlling the diagenetic fate of organic matter (Colombo et al., 1996). Organic matter in marine sediments is composed of labile and refractory compounds, whose relative importance of changes as a function of a complex array of processes, including degradation, heterotrophic utilization, transformation, accumulation and export (Viollier et al., 2003). The labile fraction of organic matter consists of simple molecules or biopolymers; which includes carbohydrates, lipids and proteins, which are assumed to represent the fraction of organic matter more readily available to benthic consumers (Fabiano et al., 1995; Dell'Anno et al., 2002). The labile portion of organic matter could be suitable to assess the trophic status of coastal marine systems (Dell'Anno et al., 2002; Pusceddu et al., 2003). Refractory organic compounds like humic and fulvic acids, structural carbohydrates and black carbon constitute most of the sedimentary organic matter and are usually accumulated in marine sedimentary environments (Middelburg et al., 1999; Zegouagh et al., 1999).

The autochthonous production or external inputs of rapidly sinking particles allows the accumulation of organic matter, which have suffered a continuous process of degradation of labile compounds in the water column as well as after sedimentation (Colombo et al., 1996) resulting in preferential loss of more labile compounds (Neal et al., 1986; Wakeham and Lee, 1989). Environmental and biological factors like water column depth, rate of sedimentation, DO content, primary productivity and bioturbation have immense influence on quantity and quality of the bulk

organic matter in sediments (Danovaro et al., 1999; Fiordelmondo and Pusceddu, 2004). Estimation of the labile fraction of organic matter is crucial in assessing food quality and quantity in benthic ecological studies (Incera et al., 2003). There is no universally accepted methodology to evaluate the labile fraction of sedimentary organic matter is available, concentrations of some specific compounds have been used to estimate the nutritional value of the sediment (Buchanan and Longbottom, 1970). The nutritional quality of sediments is generally evaluated with the help of biochemical indices like concentration of protein, carbohydrate, lipids, protein/carbohydrate ratio and lipid/carbohydrate ratio (Dell'Anno et al., 2000; Dell'Anno et al., 2002).

The biochemical composition of sedimentary organic matter in the study region showed a dominance of lipids followed by proteins and carbohydrates. The higher concentrations of sedimentary lipids, proteins and carbohydrates recorded in the study area. The total lipid recorded its maximum at S12 (POM 08), protein and carbohydrate content was maximum at S14 (POM 09) which could be related to the morphodynamic, hydrological and physicochemical characteristics. ANOVA results revealed highly significant spatial and seasonal variation for lipids ($p<0.01$). The seasonal average contribution of labile organic matter (LOM) to total organic matter (TOM) in the sediments was: 22.19±13.14% (POM 08); 17.37±8.2% (PRE 09); 17.10±8.3% (MON 09); 15.28±8.9% (POM 09); 30±19.41% (PRE 10). Present investigation revealed the fact that irrespective of the higher content of total organic matter, the contribution of labile organic matter towards total organic matter was low, comparable with previous reports (Joseph et al., 2008; Renjith et al., 2012). Hence the

sediments of the study area comprised of large amount of refractory material (uncharacterised material).

Sedimentary protein concentrations reflect the productivity of marine ecosystems and it appears to be a good descriptor of the trophic status of the benthic systems at different spatial scales (Danovaro et al., 1999, 2000; Dell' Anno et al., 2002). Like proteins, lipids also indicate the productivity of the system (Gremare et al., 1997). Carbohydrates are polyhydroxyllated compounds, ranging in size from 5-6 carbon sugars to large biopolymers (starch, cellulose), and their concentration is found to be much higher in vascular plants compared to algae (Cowie and Hedges, 1984). The dominance of lipids and protein over carbohydrates indicated the nutritive value as the freshness of the labile organic matter in the sediments of the study region.

The most abundant nitrogen containing substances in organic matter like proteins and peptides, have been regarded as part of the labile fraction in the environment, although recent studies have shown that proteinaceous material can resist microbial degradation in sedimentary environments and consequently a portion of the nitrogen is incorporated into biologically refractory organic material and removed from the active nitrogen pool (Nguyen and Harvey, 2001; Joseph et al., 2008). The occurrence of higher fractions of labile nitrogen point towards the high nutritional quality of the sediments in the study area.

In the present study, the maximum concentration of protein was found in sediments collected during POM 09. The study revealed that the organic matter is mostly of terrestrial origin and make profound influence in the biogeochemical processes. The high turnover of protein and other organics such as lipids and carbohydrates in the sediments could be due to

the decomposition of organic matter in phytoplankton and in domestic waste water. The wastes from fish peeling and processing units are dumped into the water bodies and these animal tissues undergo decomposition and liberate proteins which are adsorbed onto the sediments. A decrease in the concentration of proteins during monsoon may be due to the preferential utilization of protein by the benthic organisms and biological activity (Bhosle and Dhople, 1988). Clayey silt and silty clay sediments were capable of adsorbing more organics than the sandy ones. Generally, in estuarine sediments a predominance of silty clay or clayey silt nature during pre and post monsoon and reason for lower protein in sediments during MON 09 could be due to the input of sandy sediments from land run off. ANOVA revealed only significant spatial variation ($p<0.05$) for protein.

Lipids, the main class of organic matter in algal material (Sun et al., 2002), are well suited for source characterization of organic matter on account of the fact that they are less labile than carbohydrates and proteins and are thus often used as biomarkers to determine the sources (Volkman, 2003) and to assess the degradation of organic matter (Wakeham, 1995). Due to the presence of chlorophyll, which is a very efficient photosensitizer (Foote, 1976; Knox and Dodge, 1985), visible-light induced photosensitized processes act intensively during the senescence of phytoplanktonic cells.

Biochemical components in sediments generally undergo mineralization process in the following order: LPD >PRT >TN>TOC>CHO (Colombo et al., 1996). The application of PRT/CHO and LPD/CHO as indicators of the status of biochemical degradation processes is well established (Galois et al., 2000). PRT/CHO was found to

be maximum at S2 during PRE 09 and minimum at S6 during PRE 10. Protein to carbohydrate ratio (PRT/CHO) is used as an index to determine the origin of material present in sediments and to distinguish between the presence of fresh materials and age of sedimentary organic matter (Danovaro et al., 1993; Cividanes et al., 2002). Dominance of carbohydrates and lower PRT/CHO ratio (< 1) is a typical feature of detrital heterotrophic environments (Danovaro, 1996). PRT/ CHO ratio can also be used for classifying benthic trophic status which in turn reflects patterns of nutrient enrichment (Dell' Anno et al., 2002). In the present investigation, the estimated PRT/ CHO ratios having values <1 indicated the presence of aged or less degradable organic matter (refractory organic matter). The higher PRT/ CHO ratios in some stations of the study indicated living organic matter or "newly-generated" detritus (Danovaro et al., 1993) because proteins are more readily used by bacteria compared to carbohydrates (Williams and Carlucci, 1976; Newell and Field, 1983) and revealed the role of proteins as potentially limiting factor for the benthic consumers (Fabiano et al., 1995).

In the present investigation, maximum value for LPD/ CHO ratio was found in sediments collected from S2 during POM 08 and the minimum at S3 during MON 09. The lower values of this ratio might be attributed to the higher concentration of carbohydrates derived from allochthonous sources. The lipid content and lipid to carbohydrate ratio (LPD/ CHO) have been used as good indices to describe the food quality of the organic contents in the sediments (Fabiano and Pusceddu, 1998; Grémare et al., 2002). Furthermore, lipid concentrations have been associated with the most labile fraction of sedimentary organics and it is

considered as the best descriptor for meiofauna abundance (Cartes et al., 2002; Grémare et al., 2002).

Biochemical composition of organic matter in sediments have widely been employed as a tool to evaluate the trophic status of coastal marine systems (Dell' Anno et al., 2002; Pusceddu et al., 2003; Renjith et al., 2012). Trophic status of an aquatic system can be evaluated on the basis of both PRT and CHO trophic thresholds: hypertrophic (PRT >4.0 mg/g, CHO >7.0 mg/g, PRT/CHO >1), eutrophic (PRT = 1.5-4.0 mg/g, CHO = 5.0-7.0 mg/g, PRT/CHO <1) and meso-oligotrophic (PRT <1.5 mg/g, CHO <5.0 mg/g, PRT/CHO <1). The present investigation revealed that the trophic state of the study area can be included under meso-oligotrophic (Dell'Anno et al., 2002; Renjith et al., 2012).

Stoichiometric ratios of nutrients are utilised to determine the origin and transformation of organic matter based on the generalization that organic matter derived from marine plankton has atomic C/N ratios between 4 and 10 while higher plants have C/N ratios of 20 and above (Prahl et al., 1994; Jennerjahn and Ittekkot, 1997; Yamamuro, 2000). However the selective degradation of the different minerals in sediments can affect the C/N ratios of organic matter (Muller, 1997). In shallow coastal ecosystems, most of the organic carbon and nitrogen produced by microphytobenthos and macroalgae rather than phytoplankton (Lucas et al., 2000). Organic matter should have a C/N ratio lower than 17 for the nutritional use to invertebrates (Russel-Hunter, 1970). The C/N ratios estimated for sediments of this study area were comparable with estuaries and other similar aquatic environments (Verma and Subramanian, 2002; Joseph et al., 2012; Renjith et al., 2012). The seasonal average values of C/N (table 3.5) indicated a mixed origin of organic matter ie.

Autochthonous as well as terrestrial input. Considering the system as a whole, during PRE 09 and MON 09 showed values more than 17. Organic matter should have a C/N ratio lower than 17 have nutritional use to invertebrates (Russel-Hunter, 1970). However, the selective degradation of the different minerals in sediments can affect the C/N ratios of organic matter (Muller, 1997).

It has already been established that chlorophyll a and other phytoplankton pigments are effective indicators of fresh phytoplankton inputs to sediments (Sun et al., 1991; Josefson and Conley, 1997). The higher chlorophyll content in the sediments of the study area pointed towards the higher primary production, settling of the pigments to sediment and their preservation due to anoxic conditions. In the absence of effective number of grazers, the organic matter synthesised by primary producers are not transferred to higher tropic level leading to the settling of the excess chlorophyll to the sediment (Jyothibabu et al., 2006).

The tannins and lignins are high molecular weight polycyclic aromatic compounds widely distributed in the plant kingdom (Schnitzer and Khan, 1972; Finar, 1976; Field and Lettinga, 1987). Lignin is regarded as a nitrogen-free co-polymer of phenyl propenyl alcohols and widely occur in vascular plants. Because of the exclusive association with higher plants, lignin is usually considered as a specific tracer of terrestrial plant remains. Tannins occur in plant leaves, roots, wood, bark, fruits and buds (Kraus et al., 2003), and are estimated to be the fourth most abundant compound types produced by vascular plant tissue after cellulose, hemicellulose and lignin (Hernes and Hedges, 2000). The quantification of tannin and lignin (phenolic compounds) in sediments provide information on the input of land-derived organic detritus in marine systems. The

estimation of tannin and lignin content in sediments has been used to determine the relationship between allochthonous and autochthonous origin of organic matter in aquatic systems. The present investigation recorded the occurrence of higher concentration of tannin and lignin in the sediments which could be attributed to the input of terrestrial higher plant debris associated with land runoff.

3.3 Conclusion

Values of pH in both surface and bottom waters remained slightly alkaline at all the stations. Higher values for pH might be due to the influence of seawater ingression or increased photosynthetic activity. Wide fluctuations in the values of transparency might be due to discharge of water due to floating sediments carried by the river from catchment areas as well as dredging operations in Cochin estuary. Higher content for dissolved oxygen was recorded during monsoon, which could be due to the cumulative effect of higher wind velocity joined with heavy rainfall and the resultant freshwater mixing. The combined effects of higher biological production coupled with sinking of organic matter, discharge of untreated effluents, wastes from aquaculture fields and agricultural fields into the backwater system have contributed to the increased BOD levels in the study area. In the present investigation, no vertical stratification for salinity was observed and fresh water conditions were prevalent during the monsoon and the estimated higher values during post monsoon season could be due to increased rate of evaporation and sea water ingression. Among nutrients, ammonia displayed a non-uniform distribution throughout the entire study period which indicated an exogenic input in the estuary. The increased nitrate level was due to fresh water inflow, organic decomposition and terrestrial run-off during the monsoon season.

The lower contents of nitrite during the premonsoon season were due to less freshwater input, higher salinity, higher pH and also uptake by phytoplankton. The higher phosphate content in the water column could be attributed to regeneration and release of total phosphorus from sediment into the water column by turbulence mixing. Silicate exhibited significant negative correlation with salinity, suggesting its input through land runoff.

Texture analysis provided an insight into the grain size of the sediments in the study area. Higher concentration for organic carbon reported at some stations could be attributed to the settling of the terrigenous organic matter derived from land runoff and the minimum during monsoon could be attributed to the dilution effects associated with high river discharge associated with heavy rain. The average TOC/ TS values indicated the periodic anoxia nature of the system where, the sediments undergo sulphate reduction below an oxygenated water column. Fractionation of nitrogen and phosphorous in sediments were carried out to evaluate their various forms and enrichment character. The lower values for C/P and N/P ratio indicated enrichment of phosphorous in sediments of estuarine system. Phosphorus fractions were analyzed to quantify different fractions of phosphorus in the estuarine sediments in order to assess the processes leading to the fractional distribution of phosphorus its bioavailablity and influence on trophic status. Iron-bound IP fraction was found to be the main phosphorous pool in the estuary.

Biochemical composition of sedimentary organic matter in the study region showed a dominance of lipids followed by proteins and carbohydrates. Sedimentary protein concentrations reflect the productivity of marine ecosystems and it appears to be a good descriptor of the trophic status of the benthic systems. Lipids in sediments also indicate the

productivity of the system (Gremare et al., 1997). The dominance of lipids and protein over carbohydrates indicated the nutritive value as the freshness of the labile organic matter in the sediments of the study region. PRT/CHO and LPD/CHO ratios were useful to evaluate the quality and quantity of organic matter in the estuarine sediments. Estimated PRT/ CHO ratios having values <1 indicated the presence of aged or less degradable organic matter (refractory organic matter). Lower values of LPD/CHO ratio might be attributed to the higher concentration of carbohydrates derived from allochthonous sources. The present investigation revealed that the trophic state of the study area can be included under meso-oligotrophic (Dell'Anno et al., 2002; Renjith et al., 2012). The higher chlorophyll content in the sediments of the study area pointed towards the higher primary production, settling of the pigments to sediment and their preservation due to anoxic conditions. The average values of C/N indicated a mixed origin of organic matter ie., autochthonous as well as terrestrial input. The higher tannin and lignin content in the estuarine sediments could be attributed to the input of terrestrial higher plant debris associated with land runoff.

Chapter 4

NUTRIENT DYNAMICS ON TROPHIC STRUCTURE AND INTERACTIONS

Contents

Nutrient levels are important determinants of biodiversity, influencing the processes of competition and community structure in the water bodies. In the pelagic waters, concentration of inorganic nutrients such as nitrate, phosphate and silicate in the water dictate population growth of planktonic primary producers. Nutrients are generally considered to be the limiting factors for phytoplankton productivity. The nutrient content of estuaries is determined by their concentration in the riverine and coastal water sources. Generally nitrate, nitrite, phosphate and silicate are regarded as essential nutrients for plankton growth which affects the survival and population fluctuation of other fauna and flora in the food chain (Pramodbabu, 2007). The changes and seasonal cycles of these nutrients control most of the biological activities in estuarine systems. The nitrogen as nitrate and phosphorus as phosphate greatly augment the primary productivity and both are essential for the survival of primary producers, yet they subsist in very small concentration in the surrounding medium.

Phytoplankton and zooplankton in water samples collected from 15 selected stations spread across the Cochin backwater system were analysed to evaluate seasonal and spatial variation in their distribution and abundance. An attempt was made to unravel the primary production ,secondary production and tertiary production of the estuarine system using phytoplankton, primary productivity, phytopigments, zooplankton and fishes. The effect of general hydrography and nutrients on trophic structure was assessed by statistical methods.

4.1 Results

Results of quantitative and qualitative analysis of phytoplankton species, primary productivity and phytoplankton pigments, zooplankton species, fish landings, gut content analysis and proximate composition are described in this section.

4.1.1. a Spatial and Seasonal Distribution of Phytoplankton

Species belonging to different groups of phytoplankton were observed in the present study. They include: Chlorophyceae, Bacillariophyceae, Myxophyceae, Silicoflagellates, Cyanobacteria, Zygnematophyceae and Desmidaceae and are presented in the tables 4.1 to 4.5. Figure 4.1 provides information about spatiotemporal variation of phytoplanktons in the Cochin backwater system.

Chlorophyceae

Among the phytoplankton studied, eleven species belongs to Chlorophyceae were identified and quantified in the present investigation during POM 08 (tables 4.1 - 4.5 and figure 4.1). The present study recorded the occurrence of *Chlorella* at all stations except at S1, S13 and S14. *Microspora* was observed throughout the entire study area except at S1. It was noticed that *Tetraspora* was recorded at almost all stations except at S4. However, *Volvox* was absent in S12 and all other species shown in the table were present in all stations during POM 08.

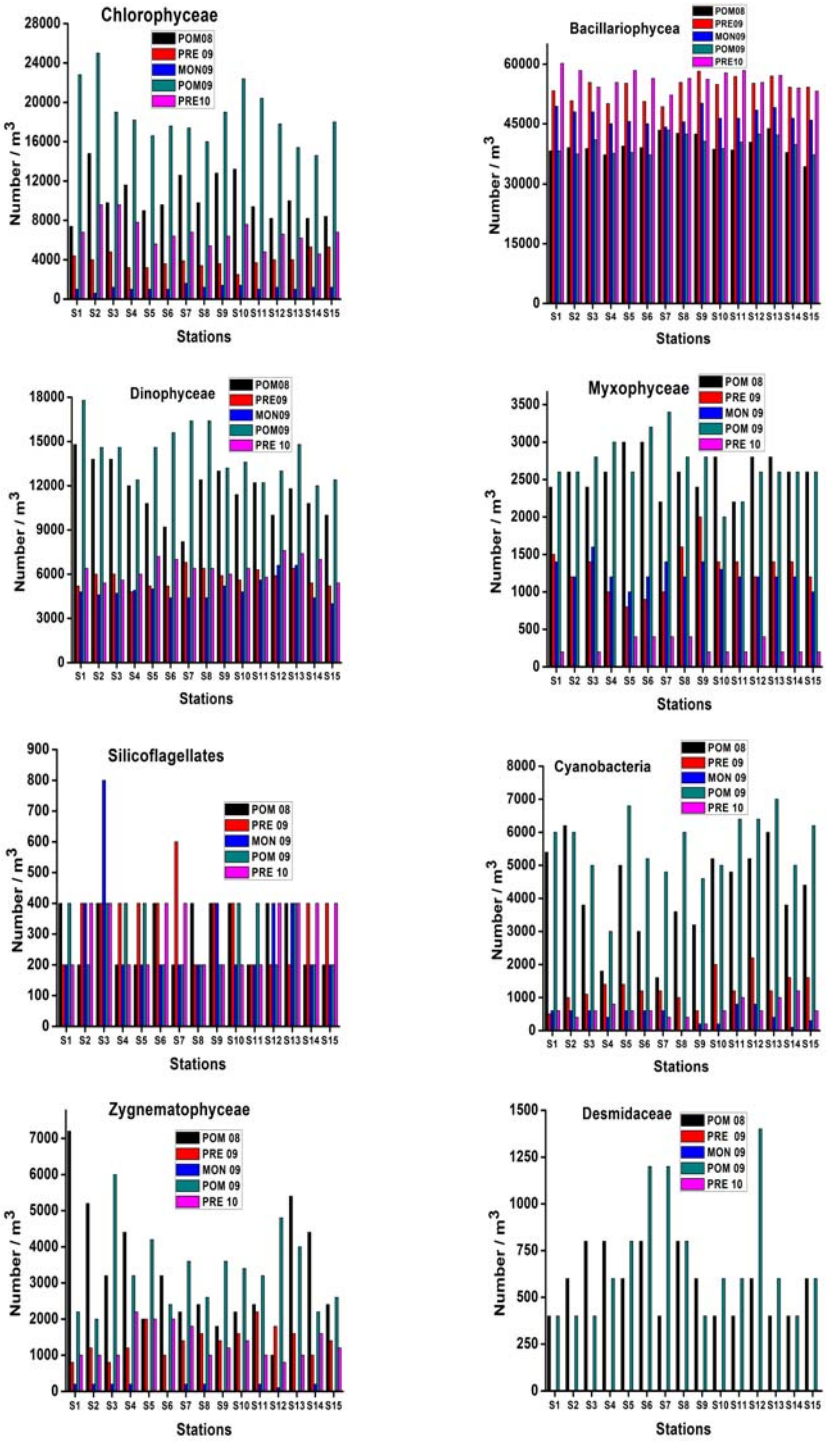

Figure 4.1 Spatial and Seasonal variation in distribution of phytoplanktons in the study area.

Ankistrodesmus falcans was present in few stations except S7 to S13 during PRE 09. *Arthrodesmus* sp.*, Micrasterias foliacea, Pediastrum duplex, Pediastrum simples, Pledorina sp.*, *Scenedesmus quadricauda, Ulothrix* sp.*, Volvox aureus* were absent in all stations. *Tetraspora* was observed at a few stations, ie. S1, S2 and S3. Among Chlorophyceae, six species were abundant in all stations and one species was common during PRE 09.

However in MON 09, occurrence of *Arthrodesmus*, *Chlorella*, *and Closterium* were recorded at all stations. All other species of phytoplaktons were absent during monsoon season. Among Chlorophyceae two species were abundant, one species was common and all others were absent in the study area.

In the present investigation, 14 planktons were identified which is shown in the table 4.4 and seen in all stations during (POM 09).

Meanwhile during PRE 10, plankton *Ankistrodesmus falcans*, *Arthrodesmus* sp., *Chlorococcum* sp., *Tetraspora* sp., *Ulothrix* sp., and *Volvox* sp., that belongs to Chlorophyceae were absent. Presence of *Micrasterias foliaceae* was observed at all stations except S8 to S15. *Microspora* was present in all stations except at S12 and S15.

Bacillariophyceae

All species belonging to Bacillariophyceae are given in table 4.6 to 4.10. *Asterionella formosa* was present in all stations except in station S5 and S6 during POM 08. *Asteremphalus flabellatus* was present in all stations except at S6. *Asterionella japonica* was present in all stations except at S6. However, most of the stations recorded *Bacillaria paradoxa*

except at stations S7, S12 and S15 during this season. It could be noticed that *Pleurosigma normanii* occurred at all stations (except S2, S3, S6, S7, S8 and S13). *Pleurosigma elongatum* was observed in all stations except in S1. *Rhizosolenia stolterfothii* was present in all stations except in S6 and S13. *Cyclotella meneghiniana* was present in all stations except at S3. *Pseudonitzschia* was present in all stations except at S15. *Thalassiothrix longissima* was present at all stations except at S9, S10 and S15. However, *Triceratium reticulatum* was present in all stations except in station S5 to S7 and S10 to S14. In the case of *Chaetoceros decipiens* presence was detected in all stations except at stations S12 and S15. *Chaetoceros denticulatum* was observed in all stations except station S3, S4 and S12. *Pseudonitzschia* sp. was present in all stations except S15. Among Bacillariophyceae, 21 species were abundant and 19 were common and others were not found in the study area of the five sampling campaigns, PRE 09 exhibited the presence of *Bacteriastrum hyalinum* at almost all stations. *Bellerochea malleus* was present in all stations except at S1. However all stations except S2 recorded *Coscinocira polychorda* and *Coscinodiscus* asteromphalus. *Fragilaria intermedia* were present in all stations except S2, S14, and S15. *Hemiaulus sinensis* was present in some stations except S1 and S4. *Leptocylindrus danicus* was present in few stations except S1, S2, and S3. Meanwhile *Lithodesmium undulatum* was present at all stations except S13, S14, and S15. Melosira sulcata was present in all stations except S6 andS8. *Pleurosigma directum* was present in all stations except S4. 32 species of phytoplankton belonging to Bacillariophyceae were abundant in the study area and 23 species were common and all others were absent during PRE 09.

During MON09 (table 4.8), *Guinardia flaccida* was found in all stations except S7, S8 and S15. *Hyalodiscus subtilis* was observed in all stations except S5 and S11. All stations of the study area recorded *Lithodesmium undulatum, Melosira sulcata, Navicula hennedyii, Nitzschia longissima, Nitzscia seriata, Pleurosigma elongatum, Rhizosolenia robusta, Rhizosolenia, Rhizosoleniastolterfothii, Rhizosolenia styliformis, Shroderella delicatula, Sleletonema costatum, Streptotheca indica, Thalassionema nitzschioides, Thalassiosira subtilis, Thalassiosira decipiens, Thalassiothrix frauenfeldii, Thalssiothrix longissima and Triceratium reticulatum*. Although *Pleurosigma normanii* was present in all stations (except S14 and S15) *Stephanopyxix palmarina* was observed in a few stations (except at S2, S6, S7, S8, S9 and S13). *Stephanopyxix turris* was found only at some stations- S1, S3, S4, S12 and S14. During this season 23 species were common and 26 species were rare 5 species were rare and all others were not observed.

Asterionella formosa was recorded at almost all stations except S5 and S6. *Bacillaria paradoxa* was seen in all stations except S4, S6 and S7 during POM 09. *Biddulphia aurita* was present at all stations except at S15. *Chaetoceros coarctatus* was found in all stations except in S8, S9, S12 and S13. *Cymbella marina* was present in all stations except S1. But few cells of *Melosira sulcata* which is a fresh water species could seen in S13, S14 and S15. *Rhizosolenia calcar-avis* was present in all stations except S1, S6, and S13, S14 and S15. The occurrence of *Rhizosolenia imbricata* was noticed in all stations except S 14. In the present study, Bacillariophyceae are the most abundant species among phytoplankton in the study area and the pigment characterization done by Aneeshkumar and Sujatha (2012) support the above finding. The presence of pigment fucoxanthin in CBW pointed out the occurrence of diatoms (Bacillariophyceae) as the most abundant group.

In the present investigation, PRE 10 exhibited the the presence of species like *Bacillaria paradoxa, Coscinodiscus concinnus, Eucampia zoodiacus, Grammatophora marina, G.undulata, Guinardia flaccida, Gyrosigma balticum* are completely absent in all stations. In the case of *Asteramphalus flabellatus* was absent in S4. *Biddulphia heteroceros* was found in all stations except S5, S11 and S14. However, Chaetoceros coarctatus was absent in S4, S11 and S13. However, *Climacodium* sp.was not seen in S5. *Coscinodiscus centralis* was present in few stations except S1, S3, S4, S9, S11, S14 and S15. *Cyclotella meneghiniana* was present in all stations except in S13. *Cymbella marina* was present in all stations except S1, S2, S11 and S15. *Fragillariopsis, Fragillaria intermedia* was observed in all stations except in S15. *Lithodesmium undulatum* was found in all stations except in S2. *Nitschia sigma* var. *indica* was present in all stations except in S15. *Pleurosigma elongatum* was absent during this season due to higher salinity exhibited during the pre monsoon. However *Thalssiothrix longissima* and *T. frauenfeldii* was recorded at all stations.

Dinophyceae

Spatial and seasonal distribution of Dinophyceae during the various seasons of the investigation period is depicted in tables 4.11 to 4.15 and figure 4.1. Among Dinophyceae, *Ceratium macroceros* was present in all stations except S5, S6 and S7 during POM 08. The occurrence of *Ceratium vulture* var. *sumatranum* was noticed in S2 and S3. *Ceratium lineatum* was present in all stations except in S11, S12, S13 and S15. Ceratocorys horrida was observed at a few stations (S2, S4, S13, S14 and S15). *Cladopyxix caryophyllum* was found in stations S2 to S8 and S15. *Dinophysis miles* was absent in stations 9, 10 and 13. The present study recorded *Goniaulux* sp. at all stations except S6, S7, and S8. *Phalacroma rotudatum* was present in stations S5, S6 and S8. *Peridinium limbatum* was present in two stations viz., S4 and S11. Among Dinophyceae, 15 species were abundant and 2 species were common and others were absent throughout the study area.

In the sampling period, PRE 09 revealed that *Ceratium tripos, Ceratium breve, Ceratium macroceros, Dinophysis caudata, Dinophysis miles Goniaulux* sp., *Ornithocerus magnificus, Peridinium claudicans, Peridinium oceanicum, Peridinium pentagonium, Peridinium steinii, Prorocentrum micans* and *Ceratium lineatum* were seen in all stations. *Amphisolenis bidentata* was present in all stations except S1 (MON 09). *Ceratium tripos* was present in S2-S4 and S15. *Dinophysis caudata, Gymnodinium* sp., *Ornithocercus magnificus, Peridinium claudicans, Peridinium oceanicum, Peridinium pentagonum*, *P.steinii, Prorocentrum micans* and *Pyrophacus horologum* were present in all stations. *Ceratium lineatum* was present in all stations except in S15. *Podolampas bipes* and *Ceratium triops* were rare during MON 09 in the study area.

During POM 09, *Ceratium macroceros* and *Ceratium vulture sumatranum* was found in all stations except S14 and S15. *Phalacroma rotundatus* occur in all stations except in S15.

Among Dinophyceae *Amphisolenia bidentata* was absent in all stations during POM09 and PRE 10. During PRE10, *Ceratium tripos* was present in all stations except S4. *Ceratium fusus* was present in all stations except in S2. *Ceratium breve* was present in all stations except S9, S10 and S15. *Ceratium horrida* and *Phalacroma rotundatus* was observed in all stations except S1. The occurrence of *Cladopyxis caryophyllum* was noticed at all stations except S1, 13, 14 and S15. Majority of the stations exhibited the presence of *Peridinium oceanicum* (except S14).

Myxophyceae

The spatio-temporal variation of Myxophyceae is furnished in figure 4.1 and tables 4.16 to 4.20. During the present study, POM 08

revealed the presence of *Katagnymene spiralis* in all stations except at S3, S9 and S11. *Trichodesmium theibautii* was observed in all stations.

However during PRE 09, *Katagnymene spiralis* and *Trichodesmium theibautii* and *Oscillatoria* sp.were found during this season throughout the study area. MON 09 revealed the presence of *Oscillatoria* sp. in the study area and their occurrence was noticed at all stations. *Katagnymene spiralis* and *Trichodesmium theibautii* were present in all stations during POM 09. Among Myxophyceae, *Katagnymene spiralis* and *Oscillatoria* sp.were completely absent in all stations during PRE 10. *Trichodesmium erythreum* was present in all stations except S2 and S4.

Silicoflagellates

Tables 4.21 to 4.25 depicts the seasonal and spatial distribution of Silicoflagellates in the study area. Few cells of *Dictyocha fibula* could be seen in all stations during the study period. Seasonal and spatial variation of Silicoflagellates is depicted in (figure 4.1). Silicoflagellates exhibited significant positive correlation with Zygnematophyceae and significant negative correlation with Desmidaceae.

Table 4.21 Spatial and seasonal distribution of Silicoflagellates during POM 08 (No./m^3)

Cyanobacteria

Spatiotemporal variation in the abundance of Cyanobacteria is furnished in table 4.26 to 4.29. Seasonal and spatial variation of Cyanobacteria in the study area is depicted in figure 4.1. Among Cyanobacteria, *Nostoc* colony is present in all stations except S6, S7 and S8 (POM 08). Few cells of *Anabaena* sp. were observed in few stations except S4 to S10, S14 and S15. *Merismopedia* sp. was present in very few stations except S4 and S6 to S15. *Anabaena* sp. (except S9) and *Nostoc* colonies

were present at all stations during PRE 09. *Merismopedia* sp. and *Tolypothrix* sp.were absent at all stations (PRE 09). MON 09 revealed the presence of colonies of *Anabaena sp.* in all stations except at S8 and *Nostoc* colony in a few stations except S8 to S10 and S14.

Tolypothrix sp.	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

However during POM 09 *Anabaena* sp., *Merismopedia* sp., *Nostoc* colony and Tolypothrix sp., were found at all stations. Cyanobacteria recorded significant positive correlation with DO.

Among Cyanobacteria, *Merismopedia* sp., and *Tolypothrix* sp., was completely absent in all stations (during PRE 10). *Anabaena* sp., (except S9) and *Nostoc* colony in all stations were observed during PRE10.

Zygnematophyceae

Spatiotemporal variation and abundance of Zygnematophyceae are shown in figure 4.1 and tables 4.31 to 4.35. All species were absent during POM 08 except the abundant presence of S*pirogyra condensata*. Among Zygnematophyceae *Spirogyra condensata* and *Zygnema* sp. were present in all stations PRE 09. *Cosmarium* sp. was present in some stations except S6, S8, S9, S12, S13, S14 and S15. *Spirogyra condensata* was seen in S1 to S8, S11, S12 and S14 during MON 09. *Zygnema sp.,Cosmarium* sp.and *Spirogyra condensata* were present in all stations during POM 09 and PRE 10.

Table 4.31 Spatial and seasonal distribution of Zygnematophyceae during POM 08 (No./m^3)

Zygnematophyceae	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11	S12	S13	S14	S15

Desmidaceae

Desmidium sp.,was commonly present in all stations (during POM 08). However, POM 09 revealed *Desmidium* sp., as the most common species in all stations. Desmidaceae were completely absent in all stations during PRE 09 and MON 09.Spatiotemporal variation of this species of phytoplankton is depicted in figure 4.1.

The maximum population density was recorded $72x10^2$No. /m^3 for the species, *Spirogyra condensata* from S1**.** During POM 09, population density recorded its maximum ($68x10^2$No. /m^3) was observed for the same species. The study illustrates that during PRE 09, maximum population density was observed in S12 for the species *Chaetoceros affinis* ($58x10^2$ No./cells.

The highest population density recorded was $36x10^2$No. /m^3 for the species, *Coscinodiscus centralis* from S13. During MON 09, population

density recorded its maximum ($54x10^2$No. /m^3) was found for the species *Cymbella marina* in the stations S8 and S9. During POM09 it was observed that *Coscinodiscus centralis* showed the maximum population density ($66x10^2$ No./m^3).

During PRE10, the maximum population density ($56x10^2$ No./m^3) was recorded from S5, S8 and S11 for *Chaetoceros lorenzianus* and it pointed out sewage and industrial pollution as *Chaetoceros* sp., is considered as estuarine pollution algae (APHA, 2005).

The spatial and seasonal occurrence of different species of phytoplankton in the study area are shown in tables 4.36 to 4.75. Percentage contribution of each group of Phytoplankton during POM **08** was in the following order:-

S1→ Bacillariophyceae> Dinophyceae> Chlorophyceae> Zygnematophyceae> Cyanobacteria> Myxophyceae>Silicoflagellates=Desmidaceae

S2→ Bacillariophyceae> Chlorophyceae> Dinophyceae> Cyanobacteria> Zygnematophyceae>Myxophyceae> Desmidaceae> Silicoflagellates

4.1.1. b Seasonal variation in primary productivity (PP)

Spatial and seasonal variation of PP in the study area is represented in table 4.76 and figure 4.2. During POM 08, PP varied from 0.11 to 0.53 mg C/m^3/day and estimated average was 0.25±0.13 mg C/m^3/day. In PRE 09, PP of the study area ranged between 0.05 and 0.50 mg C/m^3/day and the recorded average was 0.15±0.11 mg C/m^3/day. MON 09 exhibited PP ranging from 0.03 to 0.35 mg C/m^3/day (average: 0.15±0.11 mg C/m^3/day). It was observed that during POM 09, PP in the study area varied from 0.16 to 0.63 mg C/m^3/day and exhibited an average value of 0.33±0.12 mg C/m^3/day. However in PRE 10, it exhibited a range from 0.02 to 0.38 mg C/m^3/day with an average of 0.18 ±0.12 mg C/m^3/day.

4.1.1.c Seasonal Distribution of Phytoplankton Pigments Chlorophyll a

During POM 08, concentration of Chl a in the water samples varied from 1.08(S1) to 26.22µg/L (S14) (table 4.77 and figure 4.2) with an average of 8.92±7.96 µg/L. Meanwhile in PRE 09, it ranged between 0.20 (S1) and 4.90µg/ L (S7) (average: 1.53±1.32 µg/L). During MON 09, the content of Chl a varied from 0.63 (S2) to 11.55µg/L (S15) and recorded an average of 3.0±2.76 µg/L. However during POM 09, it ranged from 2.61(S8) to 39.62µg/L (S11) (average: 9.73±9.49µg/L). While during PRE 10 concentration of Chl a in water samples ranged from 2.76 (S2) to 20.88 µg/ L (S7) and the estimated average concentration was 6.74±5.01 µg/L.

Chlorophyll b

The spatio-temporal variation of Chl b is furnished in table 4.78 and figure 4.2. During POM 08, Chl b ranged from 0.05 to 16.70µg/L with an average of 2.11±4.18 µg/L. In the case of PRE 09, it varied from 0.10 to 4.92 µg/ L and displayed an average content of 1.17±1.27 µg/L. MON 09 recorded a Chlb content ranging from 0.02 to 15.63µg/L (average: 1.99±3.82 µg/L). POM 10 exhibited Chl b of surface water varying from 0.06 to 4.67 µg/L and recorded an average content of 1.88±1.46 µg/L. However in PRE 10, it ranged from 0.21 to 3.59µg/L and exhibited an average concentration of 1.02±0.89 µg/L.

Pheophytin

Pheophytin in the water samples, during POM 08 varied from 0.45 to 6.81µg/L with an average of 1.88±1.65 µg/L. In PRE 09, pheophytin content in water samples of the study region exhibited minimum value of 0.45 and a maximum of 5.45 µg/ L (average: 1.44±1.26 µg/L). MON 09 recorded pheophytin content ranging between 0.46 and 14.07 µg/L and recored an average of 3.22±3.67µg/L. All the sites revealed a pheophytin content during POM 09 varying from 0.46 (S9) to 3.49 µg/L(S3) (average: 1.54±0.90 µg/L) and in PRE 10, it varied from 0.36(S11) to 10.89µg/L(S12) (Average: 2.43±3.08 µg/L). The spatio-temporal variation of pheophytin is furnished in table 4.79 and figure 4.2.

4.1.2 Secondary Production- Seasonal and spatial distribution of zooplankton.

The qualitative and quantitative seasonal and spatial occurrence of zooplankton species collected from the study region is furnished in the tables 4.80 and 4.81 and figure 4.3. Five types of zooplankton were identified. The major zooplankton groups from the study area were comprised of Cladocera, Copepoda, Rotifera and fish eggs. A gradual increase in the total density of zooplankton population during PRE 09 and PRE 10 played significant role in the trophic food web. Copepods were found to be the predominant groups and showed strong seasonality in abundance and diversity suggesting their dominant role in all the seasons.

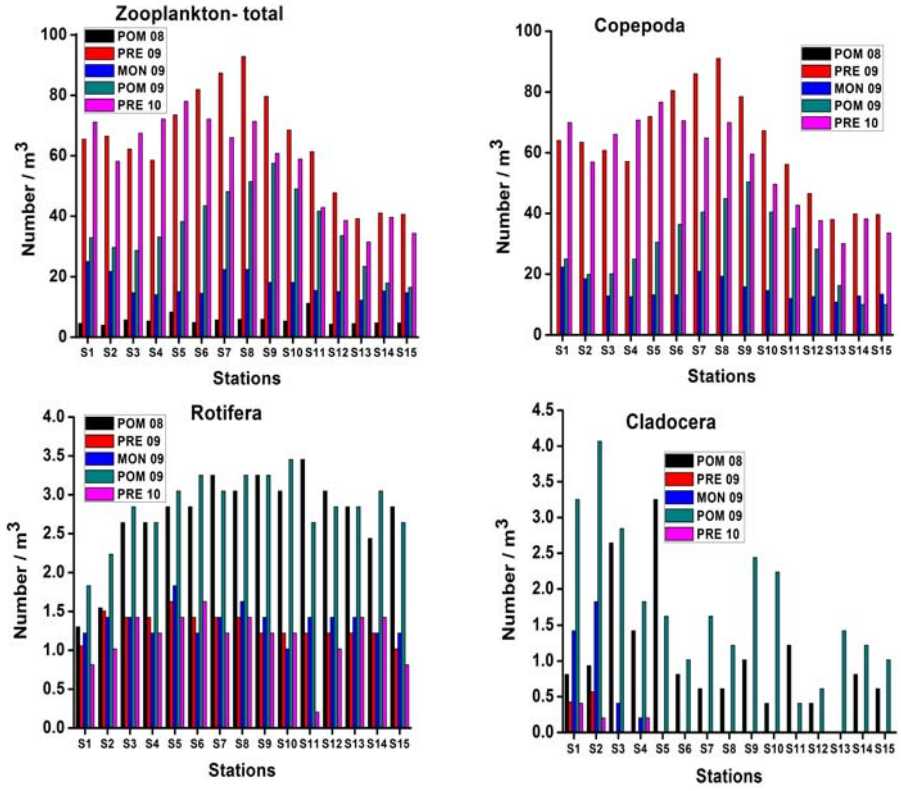

Figure 4.3 Population density of zooplankton in the study region.

S15	23.98	40.65	14.63	16.46	34.35
Total	585.08	966.77	258.33	545.12	863.21
Maximum	61.63	92.89	25.00	57.52	78.05
Minimum	23.98	39.23	12.20	16.46	31.50
Average	39.01±11.81	64.45±17.02	17.22±3.86	36.34±12.24	57.55±15.85

Total zooplankton population density during POM 08 ranged from 23.98 No./m^3 at S15 to 61.63 No./m^3 at S2(average: 39.01±11.81 No./m^3). In the present study the total zooplankton population density during PRE 09 ranged from 39.23 No. /m^3 at S13 to 92.89 No./m^3 (average: 64.45±17.02) at S8. It was observed that the total population zooplankton density during MON 09 was found to be in the range 12.20 No./m^3at S 13 to 25.0 No./m^3at S1(average: 17.22±3.86 No./m^3). It was recorded that the total zooplankton density was maximum at S9 (57.52No./m^3) and minimum (16.46No./m^3) at S15 (average:36.34±12.24No./m3).

During PRE 10, it was found that total population density showed a minimum of 31.50 No./m^3 at S13 and a maximum of 78.05 No. /m^3 at S5 (average: 57.55±15.85 No./m^3).

4.1.3 Tertiary Production

Seasonal variation in fish landings, gut content analysis and proximate composition of selected fishes were investigated.

4.1.3. a Seasonal variation in fish landings

The seasonal abundance of various fishes and crustaceans collected from the Cochin back water system is presented in table 4.82 and figure 4.4. The peak abundance of *Anabas testudineus* was in PRE 09 and minimum during POM 08. The fishes such as *Etroplus suratensis, Anguilla bicolor, Arius arius, Channa maruleus, Channa striatus, Cyprinus carpio, Etroplus maculatus, Mugil cephalus, Mystus armatus, Oreochromis mossambicus* showed its maximum during POM 09. All the crustaceans except *Macrobrachium idella* showed the peak (4760 kg) during POM 09. In the case of *Metapenaeus monoceros* maximum occurrence during POM 08(1205 kg) and minimum during MON 09 (1235kg). In the case of *Metapenaeus dobsoni,* maximum abundance was observed during POM 09.The present study reported the total landings of fishes were 260816 kg and the total landing of crustaceans was 50816 kg.

Sixteen (16) species of major food fishes and 5 crustacean species were identified in the study area and they were found to be valued and marketed in the local markets. Relative composition of various fishes and crustaceans covering the study area is presented in the table 4.82. In total out of the 16 commercially important species, *Etroplus suratensis* represented the maximum landings of 133429kg (42.82%) which is followed by *Horabagrus brachysoma* 33147kg (10.64%), *Channa maruleus* 23269kg (7.47%), *Wallago attu* 20720kg (6.65%), *Channa striatus* 17985 kg (5.77%). The minimum composition was shown by *Wallao attu* 1887 kg (0.61%). Among crustaceans *Macrobrachium idella* formed the dominant crustacean group with 20720 kg (6.65%) which is followed by *Metapenaeus dobsoni* with 10324 kg (3.31%). The total landings of *Macrobrachium rosenbergii* was7872 kg (2.53%), *Penaeus indicus* 6078 kg (1.95%), *Metapenaeus momoceros* 5822 kg (1.87%).

The reduction in prawn fisheries can be attributed to the decreasing salinity during MON 09.

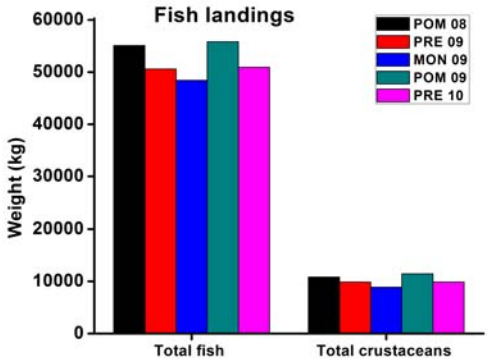

Figure 4.4 seasonal variations of total fish landings in the study area

4.1.3. b Gut content analysis

Assessment on the food and feeding habits of the fish helps us to determine its niche in the ecosystem and its preferred food items. It described how much the food spectrum of a fish overlaps with that of the coexisting fishes. The analysis of food components in the gut of a species from different ecosystem provides the information that how much that fish is flexible in feeding on different types of food items. Feeding habit is one of the primary criteria in deciding on transplantation of species to new ecosystems with least possible damage or competition to the native fauna, or its utility in overall production enhancement.

The study of the fish feeding based upon analysis of stomach content has become a standard practice (Hyslop, 1980). Mainly there are four groups of fishes based on their feeding habit viz., carnivores, herbivores, omnivores and limnivores (mud eaters). The following food fishes are used for gut content analysis.

1. *Etroplus suratensis*

The food of the pearlspot, *Etroplus suratensis* in the CBW was dominated by filamentous algae (43%) followed by detritus (35%), macrophytes (12%), diatoms (9%) and undigested molluscan shells (1%) in all seasons (table 4.83). Filamentous algae were the major food throughout the year. Feeding intensity was higher during PRE 09.

A-absent, P-present

2. Oreochromis mossambicus:

Present study revealed that the occurrence of Chlorophyceae (table 4.84), constituted 53.6%, the diatoms (Bacillariophaceae) 19.7%, aquatic invertebrates (mainly Copepoda, Cladocera and Rotifera) 12.9% desmids (Desmidaceae) 7.7% and lastly the green algae (Chlorophyceae) 6.2% observed during the PRE 09.

3. Labeo fimbriatus:

The present study revealed that *L. fimbriatus* is a herbivore. Highly coiled long intestine was observed and that indicated the herbivorous feeding habit. During POM 08, POM 09 the gut showed the presence of few species of Bacillariophyceae, Chlorophyceae, filamentous algae, detritus and mud (table 4.85). The analysis showed that during PRE 09, the presence of diatoms (Bacillariophyceae), leaves of macrophytes, filamentous algae in the gut of *Labeo fimbriatus*. Along with this vegetation traces of mud could be observed. Zooplankton and animal matter were totally absent in all seasons. The same trend was observed in the PRE 10 and MON 09 also

4. Anabas testudineus

Gut content analysis of Anabas testudineus is furnished in table 4.86. Larvae and young fry feed on both phytoplankton and zooplankton,

and adults feed on crustaceans, worms, molluscs, insect, algae, soft higher plants and organic debris (Potogkam, 1972). *A. testudineus* has been described as a predator, carnivore (Pandey et al., 1995). However gut content analysis of 25 specimens of *A. testudineus* showed that the stomach comprised of 19% crustaceans, 3.5% insects, 6% molluscs, 9.5% fishes, 47% plant debris and 1.6% semi-digested matter (Nargis and Hossain, 1987). Irrespective to spatial and seasonal distribution, major food item in the gut were found to be more or less consistent throughout the study (Nargis and Hossain, 1987) indicating *A. testudineus is* an omnivore. Insects and waterfleas were also present in some samples collected from the freshwater regime.

5. Channa striatus

Throughout the study, crustaceans, molluscs, plant parts, fish scales, algal filaments, sand and mud were present in the gut of *Channa striatus* and these fishes were distributed (table 4.87). Therefore on the basis of

different food items found in the stomach contents, *C. striatus* could be conveniently regarded as carnivore.

4.1.3. c Proximate composition of selected food fishes

Concentration of protein, carbohydrate and lipid which form the major biochemical constituents of major fishes from Cochin Back waters were estimated. In the present study, the fish species analysed individually were rich in protein (12 to 19.87%) and lipid (3.3 to 17.14%). Figure 4.5 represent the proximate composition of selected species of fishes in the study area.

Moisture Content

During POM 08, *Channa striatus* exhibited maximum moisture content (67%) (table 4.88). Minimum value was obtained from *Etroplus maculeatus* (55%). It was found that during PRE 09 maximum moisture content was exhibited by *Etroplus suratensis* (61%), and minimum was shown by two fishes viz., *Mugil cephalus* and *Arius arius* (55%). The present study revealed that *Oreochromis mossambicus* showed the minimum value (44%) and *Etroplus suratensis* exhibited the maximum (58%) in the MON 09. In POM 09, minimum moisture content was recorded by *Oreochromis mossambicus*

(49%) and the maximum was observed in *Anabas testudineus* (78%). During PRE 10, minimum moisture content observed was (53%) in the case of *Oreochromis mossambicus* and maximum (68%) in the case of *Anabas testudineus*. Moisture content during POM 08 varied from 53% to 67% (average: 61.17±5.29%), 55% to 61% (average: 56.71±2.14%) during PRE 09, from 44% to 58% (average: 52.71±4.39%) during MON 09, from 49% to 78% (average: 64.36±9.83%) during POM 09, and from 53% to 68% (average: 61.57±5.41%) during PRE 10.

Ash Content

The content of ash ranged from 3.8 to 12 % (average: 6.26 ±2.78%) during POM 08 (table 4.89). The maximum value recorded during PRE 09 was 10 % and minimum was 2% (average: 4.43± 2.64%) in PRE09. Ash exhibited variation from 2 to 10% (average: 5.57 ±2.81%) during MON 09. The minimum value recorded during POM 09 was 2% and the maximum was found to be 11% (average: 5.43±3.06%). During PRE 10, ash percentage varied from 3 to 8% (average: 5±1.73%).

During POM 08, lowest value was showed by *Arius arius* (3.8%) and highest was that of *Etroplus maculeatus* (12%). But in PRE09 minimum ash percentage was recorded by *Anabas testudineus* (2%) and recorded highest value was 10% in the case of *Etroplus maculeatus.* In MON 09, minimum ash content was exhibited by *Etroplus maculeatus* (2%) and maximum by *Oreochromis mossambicus* (10%). While in POM 09 minimum value (2%) was showed by *Anabas testudineus* and maximum value was 11% in the case of *E.maculeatus.* Meanwhile during PRE 10, minimum content (3%) was recorded by *Channa striatus* and the maximum ash content was recorded by *Etroplus suratensis* (8%).

Lipid Content

Mugil cephalus exhibited maximum lipid content (10%) and the minimum concentration was exhibited in two species *Etroplus maculeatus* and *Etroplus suratensis* (4%) during POM 08 (table 4.91). *Anabas testudineus*, *Oreochromis mossambicus* and *Mugil Cephalus* recorded minimum content (16%) and *Etroplus maculeatus* exhibited the maximum (20%) in the PRE 09. In MON 09, minimum lipid content was recorded by *E.maculeatus* (1.4 %) and maximum was shown by *Arius arius* (7%). During POM 09, minimum content ranged from 1.7% (*Etroplus maculeatus*) to 11% (*Oreochromis mossambicus*). But in PRE 10, minimum lipid content (4.8%) was observed in the case of *Etroplus suratensis* and maximum (17%) in the case of *Oreochromis mossambicus*.

During POM 08, it ranged from 4 to 10 % with an average of 6.62±2.33%. Lipid content varied from 16 to 20 % and estimated average was found to be 17.14±1.46% (during PRE 09). The range of lipid ranged from 1.4 to 7% and recorded average was 3.33±1.8% (MON 09). But in

POM 09 minimum content observed was 1.7 and the maximum was found to be 11 % (average: 4.74±3.23%). In the present study, minimum lipid content was found to be 4.8% (*Etroplus suratensis*) and maximum was 17% (*Oreochromis mossambicus*) (average: 8.77±4.72%) in PRE 10.

Protein Content

During POM 08, it was observed that protein content varied from 13 (*Etroplus maculatus*) to 30% (*Oreochromis mossambicus*) with an average of 19.87±5.98% (table 4.92). It was found that PRE 09 recorded a minimum of 12% (*Etroplus maculeatus*) and maximum of 25% (*Oreochromis mossambicus*) and exhibited an average concentration of 18.83±4.25%. The minimum protein content was 9% (*Channa striatus*) and maximum of 16% for *Mugil cephalus* (average: 12±2.58%) during the MON 09 period. However, during POM 09 exhibited a minimum value of 11% (*E.maculeatus*) and maximum of 20% represented by *Channa striatus*. (average: 16.84±3.39). It was observed that during PRE 10, minimum

protein content was 10% (*Etroplus maculeatus*) and maximum content of 25% was estimated for *Channa striatus* (average: 18.06±4.92%).

4.2 Discussion

Cochin backwater system is a tropical estuary influenced by various stressors. The wind brings cool, oxygen deficient and nutrient rich waters towards the SW coast of India. The varying physico-chemical conditions makes the coastal waters highly fertile (Habeebrehman et al., 2008) and enhances primary production several fold higher than the offshore waters (Ryther,1963). Considering the significant role of plankton in the productivity of tropical and coastal ecosystems the present study has been undertaken to extend the knowledge on systematics, species composition, distribution, abundance and ecology of the phytoplankton, zooplankton and fishes in the

study area. In recent times it is increasingly evident that CBW faces pollution because of excessive use of pesticides, effluents, and sewage. Over the seasons, the ecosystem experiences extensive droughts in the pre-monsoon to flooding in the monsoon. Physico-chemical properties of water vary daily, seasonally, and yearly because of natural seasonal cycles. Daily fluctuations in the near shore physical environment are mainly due to tides, and biological processes like excretion. All these processes significantly affect near shore distributions and concentrations of phytoplankton.

Phytoplankton in the estuarine environments utilizes carbon dioxide for photosynthesis thereby play an important role in maintaining carbon dioxide budget of the atmosphere. The food chain of this ecosystem is drawn from primary producers through zooplankton to omnivorous and carnivorous fishes. The fishes caught from the aquatic environment are consumed by human beings thereby reducing protein deficiency. Indiscriminate exploitation of marine food source has resulted in depletion andso there should be judicious and sustainable fishing is necessary. This could be possible by quantifying the biomass of plankton, from which the fish population will be produced and calculated and finally the catchable amount per year could be predicted. Major and minor phytoplanktons identified in the study area during different seasons are furnished in tables 4.93 to 4.98.

Phytoplanktons are the assemblages of particulate plants making up the first trophic level of pelagic food chains. Phytoplankton forms the primary source of energy for all organisms from zooplankton and upto large fishes and even birds. Phytoplankton, Chlorophyll a and primary production are important determinants of the standing stock and organic productivity of a water body. These variables have often been utilized to evaluate the overall health of any particular water body (Menon et al., 2000). Diatoms are often the dominant algal group in most fresh water systems, often contributing more than half of the overall primary production. Species assemblage can be effectively used to infer past environmental changes. Phytoplankton, the basis of food chain, forms the chief index of utilisation of abiotic factors and the net productivity of the ecosystem, ultimately the extent of utilisation on these recourses at secondary and tertiary levels can be interpreted. The present study aims at obtaining more basic knowledge on distribution of pigments, describing relative contributions of phytoplankton, zooplankton and fishes in Cochin Backwaters. It would help in understanding ecological changes and

formulation of effective management strategies for the sensitive marine habitats. Enrichment of the organic matter in sediment observed in the Cochin estuary is a sign of environmental degradation. As a consequence, there has been considerable reduction in the diversity of zooplankton.

Phytoplankton diversity was more pronounced during premonsoon season, maximum density was observed during postmonsoon season due to the stable hydrographical conditions and less predation. It was also noticed that species diversity showed the following trend: PRE 10> PRE 09> PRE 09> POM 08> MON 09. *Skeletonema costatum, Cyclotella meneghiniana*

are present which are euryhaline and thus show abundance. Different species belonging to various groups of phytoplankton were observed in the present study. They are Chlorophyceae, Bacillariophyceae, Myxophyceae, Silicoflagellates, Cyanobacteria, Zygnematophyceae and Desmidaceae. During premonsoon, dominant species observed include *Coscinidiscus centralis, Coscinodiscus granii, Chaetoceros lorenzianus, Chaetoceros affinis, Thalssiosira subtilis, Streptotheca indica* and were successfully surviving the saline waters. *Asterionella japonica, Aulacoseira granulata, Cerataulina bergonii, Coscinodiscus centralis, Nitzschia longissima, Nitzschia seriata, Thalssiothrix frauenfeldii* are dominating and it is understood that salinity controls these phytoplankton density and succession. During postmonsoon, gradually the fresh water species disappear coinciding with the predominance of marine forms. *Trichodesmium theibautii* was absent duing rainy season due to the fresh water influx and it could actively grow within optimal salinity range (Sinha et .al., 1996, De et.al 1994, Jyothibabu et al., 2003). The analysis of physicochemical parameters in the water column revealed that the system is oligomesotrophic similar to the earlier reports by Renjith et al., 2012. The results of phytoplankton were comparable with the earlier records (table 4.98). The size structure provides useful insight into the ecosystem functioning as the larger phytoplankton are generally dominant in nutrient-rich, productive waters whereas smaller phytoplankton are abundant under mesotropic conditions (Aneeshkumar, 2009). In the present study, fractionation of P and N in sediments and the elemental ratios estimated as described in Chapter 3, pointed towards the enrichment of P in this estuarine system.

The synthesis of organic compounds from the inorganic constituents of sea water by the photosynthetic activity of green plants is termed as primary production, and traces of organic matter also formed by chemosynthesis. The raw materials are water, CO_2, the nutrients mainly nitrate and phosphate. Plants making use of light energy are able to combine these simple substances to synthesise complex organic molecules. The chief products are the three major categories of food materials namely carbohydrates, proteins and fats. The consumption of plants by herbivorous animals leads to the formation of animal tissue, which in turn becomes the food for the first rank of carnivores and so on. These successive stages of production of living tissue form a series of trophic levels or links in the food chain being interconnected and forming an intricate food web. Eventually as a result of respiration, excretion, death and decomposition, the organic materials undergo break down and are returned to the water as simpler substances which can be utilised by organisms. In this way matter is continually cycled from inorganic to organic forms and back to inorganic state. It is essential to measure the primary production in the aquatic environment to assess the total primary productivity and potential fishery resources.

The rate of PP in an ecosystem is depending on various physical and chemical parameters. The onset of the southwest monsoon varies from year to year and so rainfall contributes to the variability of the estuarine water levels, flow and chemistry. Thereby the water quality plays an important role in selecting the phytoplankton community (Chavez, 1996; Legendre and Le-Fevre, 1989, Moore and Abott, 2000). PP showed significant positive correlation with Chlb, NO_2 and highly significant positive correlation with transparency and Cyanobacteria during PRE 09. In MON

09, primary prodductivity exhibited significant positive correlation with ammonia and pH. The low values of primary productivity during MON 09 is due to freshwater discharges from the rivers, land runoff, leading to turbidity and high value of light extinction coefficient and less availability of light [Kawabata et al., (1993); Godhataraman, (2002); Thillai Rajasegar et al., (2005)]. Primary productivity displayed highly significant positive correlation with pheophytin and iron during POM 09. Two way analysis of variance (ANOVA) revealed that there was high spatial and seasonal variation ($p<0.01$) in surface waters. In bottom waters two way ANOVA showed highly significant seasonal variation ($p<0.05$). The currently recorded high PP during POM 09 and PRE 09 could be attributed to high light intensity, clear water condition and nutrient availability as stated in the earlier reports (Gopinathan et al., 1994), Thillai Rajasegar et al., (2005). In the present study the observed low value during POM 09, could be due to the uptake of silicates by planktonic organisms (Mishra et al., 1993; Ramakrishnan et al., 1999). The recorded lower primary productivity during MON 09 could be due to the wash out of phytoplankton by the monsoonal floods, thereby reduction in salinity which could affected the phytoplankton population and lowering of PP during MON 09 and these findings are in concordance with the earlier reports (Rajasegar et al., 2000, Gowda et al 2001, Thillai Rajasekar et al., 2005).

In estuaries, quantitatively phytoplankton are the second source of particulate organic matter after terrestrial inputs from soil erosion which supply the highest quality food source and constitutes premier basis of the estuarine food web (Gasparini et al., 1999; Burdloff et al., 2000). The phytoplankton biomass contains: chlorophyll a, b and its degradation products, pheophytin. It is a marker of organic carbon (Bianchi et al.,

1995) and is present in all phytoplankton species; it can serve, as a measure of changes in their biomass. Pigments like Chl a, Chl b and pheophytin in seawater are good markers of different processes taking place in the water column, principally grazing by heterotrophic organisms (Welschmeyer and Lorenzen, 1985). Chlorophyll a derivatives, especially of pheophorbides a, are indicators of intensive activity of these organisms (Bianchi et al., 2002). Chloropyll a (Chl a) can be used as a global algal biomass indicator. Chl a is present in all groups of photosynthetic organisms except some bacteria (Moss, 1968). Cermeno et al., (2006) suggested that large-sized phytoplankton have greater potential to export organic matter through a short classical food chain, whereas the small-sized phytoplanktons are utilized by complex microbial food webs that favour the recycling of organic matter. Many studies have confirmed that small sized phytoplankton is an integral component in environmental monitoring assessment of the plankton community. Their relative contribution to the total community varies with the abundance of large-sized phytoplankton (Raimbault et al. 1988). Increase of diversity and evenness in offshore communities of low biomass is common (Madhupratap, 1987). According to Madhupratap et al., (1990) the occurrence of increased biological productivity during monsoon season could be due to river run off. Generally, nutrient enrichment favours the growth of large phytoplankton, while the production of small phytoplankton is mainly controlled by microzooplankton (cilites and flagellates) grazing (Jyothibabu et al., 2006).

Pigments are bound in pigment-protein complexes as part of the light harvesting complexes of reaction centres in autotrophs (Porra et al., 1997). Chemical structures of pigments and properties have been extensively reviewed (Young and Britton, 1993; Scheer, 2003), as have

their metabolism (Porra et al., 1997) and applications in oceanography (Jeffrey, 1997). Comprehensive data and graphic sheets were compiled for most important chlorophylls and carotenoids present in marine algae (Jeffrey and Vesk, 1997). Chlorophylls are more susceptible to biological breakdown than the carotenoids (Porra et al., 1997) and are explained by many workers (Brown et al., 1981, Scheer, 1991 and Kowalewska et al., 2004) and most of these breakdown products are easily detectable by regular pigment analysis. Chlorophyll a is a ubiquitous pigment and can be used as a global algal biomass indicator. It is present in all groups of photosynthetic organisms except some bacteria (Moss, 1968). Chl b was the next important pigment detected in low concentration.

In the present study, Chl a value was maximum during the POM 09 at S11 (39.62µg/L) which is a thickly populated semi urban area having sewage disposal and waste dumping taking place and it lead to eutrophication and lowest value was 0.20µg/L at S1 during PRE 09 which is a fresh water zone (riverine area). The variation in concentration of this pigment in the present study was generally associated with environmental factors, especially inflow of freshwater during rainy season, light and nutrient availability. Earlier studies revealed that mean Chl a concentration in the estuarine and coastal waters vary with respect to other aspects (Selveraj et al., 2003; Renjith, 2006). In the Cochin estuary, the Chl a content have been reported as 2 to 21µg/L (Nair et al., 1975), 4.93 to 8.93 µg/L (Selveraj et al., 2003) and 1 to 34.61 µg/L (Renjith et al, 2006), 2.75 to 17.97 µg/L (Aneeshkumar, 2009). The estimated Chl a value recorded in the present study showed comparatively lower values with the earlier reports (table 4.99). Observation of higher Chl content during premonsoon and postmonsoon seasons in the present study agree with the earlier

observations by Gopinathan (1972), Devessy and Bhattathiri, (1974) in Cochin estuary. Estimation of photosynthetic pigments of plankton of the Cochin backwaters has brought out contrasting results. Nair et al., (1975) have estimated an overall range of 1.5–18 mg m-3 for Chl a. The findings of Joseph and Pillai (1975) indicated that maximum Chl a concentration for pelagic flora occurs during monsoon, whereas for benthic microflora, the maximum were reported during premonsoon and monsoon (Sivadasan & Joseph, 1995). In this study, transparency and CO_2 showed highly significant positive correlation with Chl a supporting the highly productive nature of the system due to these factors during POM 08. Chl a showed significant negative correlation with Desmidaceae. The estimated average Chl a content was in good agreement with the previously reported works (Martin et al., 2012). The high biomass of Chl a in the study area are possibly due to the enrichment of nutrients by industrial and domestic activities (Jyothibabu et al. 2006; Madhu et al., 2007). The anthropogenic activities have lead to an increased production of chlorophyll a in the estuary. Moreover, the high organic productions are not transferred to the higher tropic level due to the lack of effective grazers, which leads to settling of the excess chlorophyll to the sediment (Jyothibabu et al., 2006).

Table 4.99 Previous studies on Chlorophyll a in Cochin backwater system.

Area	Chl a µg/L	Reference
Cochin	1.5 to 18	Nair et al., 1975
Surf Zone Cochin	8.35 to 15.64	Selveraj et al., 2003
Cochin estuary	4.93 to 8.85	Selveraj et al., 2003
Off Cochin	1.0 to 5.0	Gopinathan et al., 2001
Cochin Back water	1 to 34.6	Renjith et al., 2006
Cochin Back water	1.7 to 47.0	Madhu et al., 2007
Cochin Back water	2.75 to 17.97	Aneeshkumar, 2009
Cochin Back water	5 to 49	Martin et al., 2012
Cochin Back water	1.53 to 9.74	In the present study

Chlorophyll b, also exhibited the same trend, in the entire sampling sites with slight variations in some stations. Moderately higher concentration was observed at all stations in all seasons under study.

The environmental factors that strongly influence pigmental composition of phytoplankton are irradiance (Schlüter et al., 2000., Henriksen, 2002), Spectral distribution of light (Partensky et al., 1993), day length (Sakshang et al., 1986), diurnal cycle (Tukaj et al., 2003), nutrient status (Henriksen et al., 2002), iron concentration (Van Leeuwe et al., 1998), growth phase (Schlüter et al., 2000 and strain differences (Stolte et al., 2000; Zapata et al., 2000).

The amount of pigments and nutrients in the water column are the key factors for determining the biological productivity and potential resources. The transparency and the nutrients indicate the fertility of the water body for the enhancement of primary productivity and the availability of the photosynthetic pigments and phytoplankton. The peak production was coinciding with the periods of low nutrient concentration have been observed by Qasim, (1980) and Jagadeeshan, (1986) in Cochin back waters, Cuddalore, Uppanan back waters and Coleroon estuary and the same trend could be observed in the present study. Insignificant correlation between nutrients and primary production pointed out the fact that in spite of the higher concentration of available nutrients in water column; the productivity was restricted by factors like transparency and meteorological factors. Moreover nutrients available in the water column are not fully utilized by the phytoplankton.

Plankton particularly has been used as indicators of water quality (Palmer 1969; Stoermer and Yang, 1969). Copepods and other zooplankton groups and the larval forms of many bottom living and pelagic marine

animals appear to be herbivorous grazing on phytoplankton. Through all these ways plankton are very much beneficial but some of them cause deleterious effects on the ecosystem due to algal bloom (Martin et al., 2011).

Variability in plankton is enormous and is dependent on the changes in the environment. Thus with the changing environment it is only natural to expect the variations in the composition of plankton and this variability provides the only source of information about the dynamics of natural population of plankton. The numerical abundance of a species at a given locality in the ocean is the result of interaction between a number of factors like water transport, change in temperature, availability of food, diurnal vertical migration, rate of production, age of the ecosystem and the survival.

The study of the zooplankton biomass is helpful to determine the potential fishery resource of a nation and the relative fertility of the water bodies. So regular monitoring of plankton is necessary to know the fishery potential. Because of their worldwide distribution, abundance and dominance, copepods are most significant secondary producers (Gaonkar et al., 2010). The zooplanktons are considered to be the cattles of the sea. They are the grazers feeding either on the phytoplanktons (herbivorous) or on other zooplanktons (carnivorous). In that way they actually contribute to the transfer of energy to other organisms in the oceans. Being the primary consumer, they have a key role in the sustenance of higher forms of life in the oceans. In many cases the plankton serves as indicator organisms for water quality, temperature profile and nutrient richness of the water column.

The ecological role of an organism is largely determined by its position and significance in the food web. The zooplanktons are important in marine food chain as it plays a dual role as phytoplankton consumers and contributors to the higher tropic level. Primary trophic level can be directly connected to the next level or through the animal plankton or zooplankton. Zooplanktons are primary consumers, simply the grazers on phytoplankton in pelagic ecosystem models. Zooplanktons are secondary producers, so to assess the biomass at this trophic level to determine the rates of secondary production.

The potential cause of higher production of fishes is basically due to the higher plankton abundance which is determined by many other factors such as physical and chemical parameters of the marine environment. Species diversity can be defined as the effective number of different species that are represented in a collection of individuals (a dataset). Species diversity consists of two components, species richness and species evenness. Species richness is a simple count of species, whereas species evenness quantifies how equal the abundances of the species. The species diversity is the total number of species present at a time in an ecosystem in the same time. In the environment which is having normal ecological condition will have more species diversity than that in extreme climatic condition. The species diversity of holoplankton mainly depends on temperature, salinity, DO and water currents and other hydrographical parameters. Thus the highest diversity is found in tropical and subtropical regions and the lowest in the extreme environment such as polar zones and brackish water areas.

Majority of the aquatic feeds constitutes plankton community. Zooplankton serves as the primary source of food for the larval stages as

well as adults of many fishes and aquatic organisms of economic importance. Study of species composition is important or some species are useful indicators of the health of the environment. Presence of certain zooplanktons indicates the water quality or degradation of the environment. The fishery production of any aquatic system mainly depends on the magnitude of phytoplankton as well as zooplankton production and their interrelationship (Prasad, 1969). The secondary production in an area can be calculated by analyzing the zooplankton production. A gradual increase in the total density of zooplankton population played significant role in the trophic food web observed during PRE 09 and PRE 10. Copepods were found to be the predominant groups showed strong seasonality in abundance and diversity suggesting their dominant role in all seasons which is in accordance with the earlier studies (Madhupratap,1978, Madhu et al., 2006). Zooplanktons were abundant during high saline premonsoon period and was supported by Silas and Pillai, 1975. The salinity acts as a limiting factor in the distribution of living organisms and its variation caused by dilution and evaporation which influence the faunal composition and distribution of the coastal ecosystems (Chandramohan and Sreenivas, 1998). Experimental studies in CBW by Jyothibabu et al., (2006) have revealed that approximately 43% of phytoplankton biomass was consumed by microzooplankton per day. The increased grazing of phytoplankton by microzooplankton could be one of the reasons for a relatively low level of Chl a during PRE 09 eventhough the environmental conditions remained favourable for phytoplankton growth.

In the present investigation, copepods were present throughout year in the plankton samples and formed the dominant component of the crustacean holoplankton. Copepods like *Acartia centura, Acartia spinicauda,*

Acartia bowmani, Acartia southwelli, Acartia pacifica, Acartia plumosa are present during all seasons and disappear during rainy season.The intimate relationships of Cladocera with fisheries were reported by Yahia et al., (2004). It was observed that the percentage incidence of cladocerans was 0.09 to 4.92%. The dominance of cladocerans were in the order POM 09>POM 08>MON 09>PRE 10>PRE 09. The dominance of cladocerans during postmonsoon period was reported earlier (Bhat 1979, Patil, 1987) in Nethravathi-Gurupur estuary. The percentage incidence of copepods, which are vital components of secondary producers, was between 79.38 to 97.30% and the percentage was maximum during PRE 09.

The maximum percentage incidence of rotifer was during MON 09. Pattil, (2002) attributed the dominance of rotifer to the absence of predator fishes. Unlike crustaceans, rotifers feed on bacteria and detritus, which make them less dependent of autotrophs (Ruttner Kolisko, 1974). Increase in rotifers during MON 09 was noticed in the study eventhough the phytoplankton and primary production was minimum as rotifers are less dependent on phytoplankton (Castro et al., 2005). During PRE 09 and PRE 10 another peak was observed due to the migration of some migrant species to the estuary.

The faunal composition showed fall in density during MON 09 and gradual repopulation leads to another peak during POM 08 and POM 09. The fish eggs were maximum during POM 09 and POM 08. The zooplankton distribution in the back waters suggests that the salinity is the major limiting factior controlling their abundance. All groups showed remarkable seasonal distribution with respect to changes in salinity and other environmental factors. The present investigation is in good agreement with the earlier investigation, which states that the population density of

zooplankton in the estuary is no way limited by primary production, which through out the year far exceeds the consumption by zooplankton (Menon et al., 2000). According to Qasim et al., (1969), the primary production in CBW was maximum at the surface during monsoon and post monsoon seasons, while during premonsoon season, it covers subsurface layers too. It has been reported that the primary production in the estuary exceeds zooplankton several folds (Atkinson and Dhreeve, 1995, Madhu et al., 2007). In the present study, the action of tidal currents and rainfall are most important.

Fish landing depends on environmental and the socioeconomic factors and fishery dependent factors such as fishing effort, type of craft, gear and mesh size. Rapid changes in the environment due to uncontrolled human interventions lead to depletion of the rich fishery resources of Vembanad Lake. The well being of large community depends upon these resources for livelihood and nutritional needs are currently under grave threat. It is necessary to assess the status of fishery with the intention of creating awareness about this situation.

Algal production acts as a biostimulation for the enhancement of fish production. Aquatic systems, especially the backwaters, are storehouses of cheap protein rich diet. Aquatic life is continuously under the threat of various stressors of environment which include exposure to contaminants, unfavourable temperatures, water velocities, sediment loads, hypoxia, reduced food availability etc. These factors individually or collectively, can impose considerable stress on the physiological system of the aquatic organisms and can lead to reduced growth, impaired reproduction and susceptibility to diseases and reduce capacity to tolerate subsequent stress. Study of fish fauna helps us to obtain a deeper insight

into casual relationship between stress and its effects at the community levels. Fishes are affected by these toxic substances which lead to biomagnification. The effluents discharged from industries resulted in mass destruction of aquatic organisms in many coastal environments (Cognetti, 1999, Benovic et al., 2000). Seven landing centres adjacent to sampling sites were studied and monthly data were collected for seasonal comparison for fishes.

Some fishes are extensively zooplankton feeders and therefore the abundance is directly linked to the presence of secondary producers. The success and failure of fishery particularly, pelagic fishes depends on the availability of plankton. The overall niches are governed by the feeding spectrum and feeding types among the zooplankton, some are detritivorous some are filter feeders feeding in different size spectrum of phytoplankton organic detritus as well as on nano and micro zooplankton. The functioning of the food webs depends on the balance between bottom up and top down control. Bottom up is the resource driver control. The top down control is the predator control.

The temperature fluctuations from premonsoon to monsoon are significant and it exerts some effects on the seasonal distribution and abundance of stenohaline fishes which migrate completely from the estuary during south west monsoon (Menon et al., (2000), Kurup and Samuel, (1985a). Annual landings (1988-1989) of fishery resources form Vembanad lake was 7200 tonnes of which fishes constituted 3297 tonnes, marine prawns 3499 tonnes, freshwater prawns 118 tonnes and crab 284 tones (KSSP, 1992). Kurup and Samuel, (1987) reported that among 115 species of fishes recorded in the Vembanad lake, 77 preferred high saline areas, but during 1987 these autors recorded 103 species associated with salinity.

According to Pramodbabu(2007) the total landings of crustaceans was 42762 kg from Thanneermukkom to Thottappally. The present study was carried out from Karippadom to Kalamassery (near FACT) and the yield of fish from the entire study area was 260816 kg and crustaceans were 50816 kg. The study of fishes from the different areas of the CBW explained that high landings were always recorded from high saline regions.

The present study revealed that there is the decline in fish species that might be due to destructive methods of fishing that lead to the destruction of breeding grounds (KSSP, 1992). Pollution due to the dumping of waste water form industries and domestic sewage situated on the banks of CBW (KWBSP, 1989), dredging of lime shells, lack of salinity intrusion and disease outbreak etc. are responsible for the reduction in fishery potential. This study was helpful to reveal the present status of this ecosystem which has become extremely crucial for exploiting the brackish water fishery resources. The annual production of fishes in Kerala is unsatisfactory and the current landings from waterbodies are below the protein requirements of people in Kerala. So under these circumstances, the judicious exploitation of water resources in a scientific manner is a necessity to tackle the deficit food situation in the country.

With the onset of south west monsoon, salinity gets reduced drastically in most of the stations. This will leads to the reduction in the distribution and occurrence of fishes from the study area during MON 09 (Kurup and Samuel, 1987). Another possible reason for the decline in fishery resources is due to loss of nursery grounds of the area. The anthropogenic stress and pollution to the water bodies are causing decline in fishery. The abundance and distribution of fishes in the CBW is based on the prevailing salinity and annual rainfall (Kurup and Samuel, 1985).

The maximum landings recorded in the present study were obtained during POM 08 and POM 09 the landings were 65903 kg and 67256 kg respectively.

Gut content analysis imparts important insight into fish feeding patterns and quantitative assessment of food habits. Accurate description of fish diets and feeding habits also provide the basis for understanding trophic interactions in aquatic food webs. Diets of fishes provide a combination of many important ecological components that included habitat use, energy intake, inter and intra specific interactions (Bindu and Padmakumar, 2008). Assessment of food and feeding habits of the fish helps us to determine its niche in the ecosystem and its preferred food items. It tells us how much the food spectrum of a fish overlaps with that of the coexisting fishes. The analysis of food components in the gut of a species from different ecosystem provides the information that how much that fish is flexible in feeding on different types of food items. Feeding habit is one of the primary criteria in deciding on transplantation of species to new ecosystems with least possible damage or competition to the native fauna, or its utility in overall production enhancement. In the present study, relative length of gut ranged between 1.16 and 6.87cm indicating omnivorous feeding (Bindu and Padmakumar, 2008).

Chlorophyceae which formed the primary food of *Etroplus suratensis* were represented by *Spirogyra, Oscillatoria, Lyngbia and Fragillaria*. Diatoms, *Nitzschia, Pleurosigma* and *Navicula* were observed in the gut contents during PRE 09. Detritus, filamentous algae and semidigested materials were present as a major food constituent throughout the year. The large quantities of detritus in the diet of *E. suratensis* in the CBW, was observed in the study, pointed out the feeding behaviour of this

fish which includes detritus. In freshwater systems, detritus play a significant role in the diet of fishes (Bowen, 1981; Keshava et al., 1988). The seasonal change in the abundance of food items of *E. suratensis* is a reflection of the availability of food in the environment (Bindu and Padmakumar, 2008). During PRE 09 and PRE 10 Chlorophyceae dominated the food items, whereas detritus comprising of decayed vegetable matter formed the major item during POM 08 and POM 09. Low utilisation of planktonic food during MON 09 may be due to its poor availability owing to high turbidity resulting in low phytoplankton production. The present results agreed with the findings of Kurup, (1993) who reported that sizeable reduction in the population of diatoms and algae during monsoon months is a characteristic phenomenon in these backwaters. According to Bhatnagar and Karamchandani, (1970), the feeding intensity and diet composition of fish are apparently linked to the availability of food in the habitat. In the present study along with phytoplankton, the gut contains a variety of food items such as copepods, cladocerans, insects and worms during POM 09 (Jhingran and Natarajan, 1969)

In *Oreochromis mossambicus* the percentage occurrence of *Lyngbya* spp. *Anabaena* spp, and *Merismopedia* sp. show an increase in percentage occurrence with *Navicula sp., Melosira* sp., *Nirzschia* sp., *Anabaena sp., Microcystis sp., Merismopedia* sp., *Pediastrum* sp., *Oscillatoria* sp., *Scenedesmus* sp., *Lyngbya* sp., *Saurastrum* sp., *Cymbella* sp., *Synedra* sp., *Ceratium* sp., *Chlorella* sp., were observed in the gut contents during POM 09 and POM 10. In the case of *Oreochromis mossambicus* the most preferred food items observed during PRE 10 were *Nitzschia, Lyngbya, Microcystis aeruginosa* and *Pediastrum simplex, Melosira* sp, *Navicula* sp.

Among the zooplankton, the Cladocera and the Rotifera had low to moderate percentage in the gut. Some of the food items consumed showed an increasing trend with fish size.

Fishes of all size categories were found to be phytoplanktivores. A total of 26 microphytoplankton species were observed in the stomach contents (15 species of Chlorophyceae, 11 species of Bacillariophyceae, together with a few rotifers and some organic material). In terms of cell numbers, the overall composition of the diet was 70% Chlorophyceae, 21% Bacillariophyceae, 6% organic matter and semidigested small fishes. Neither diet composition nor stomach fullness varied with fish size. However, fish had relatively gorged stomachs, with higher proportions of Chlorophyceae, Bacillariophyceae, during MON 09. Long coiled intestine suggest the species is largely herbivorous, consuming planktonic algae and aquatic plants (Hensley and Courtenay 1980; Gonzales and Moran, 2005). Most of the fish species can be placed in the opportunistic omnivore category (Boschung and Mayden, 2004).

Proximate composition, were determined in some widely consumed fish species obtained from the CBW. The results obtained in the present study indicated that biological differences existing in fish species can influence the values to be set for the standards and composition (Guner et al., 1999). The data on proximate composition help the nutritionist, dieticians and consumers to estimate the intake of the principal nutrient in the human diet, to calculate energy values, contents of the diet and was useful to determine the difference in the nutrient value seasonally. The variation was observed from species to species. Increase in the moisture content during seasons other than MON 09 was coincided with increase in salinity. Shekhar et al., (2004) reported that moisture content differ according to season when

other constituents were low. The low values of carbohydrates recorded in the present study could be because glycogens in many marine animals do not contribute much to the reserves in the body (Jayasree et al., 1994). Ramaiyan et al., (1976) reported similar findings in 11 species of Clupeids. Phillips et al., (1967) reported that carbohydrates are utilized for energy in trout, thus sparing protein for building of the body.

The average lipid content in the fishes taken for study was maximum during PRE 09 (average: 17.14±1.46%) ie. during spawning season. Depending upon the level of lipids in the fish muscles, they are classified into three categories eg. fat fish with more than 8 % average fat content, average fat fish with fat content range between 1 % and 8 % and lean fish with fat content less than 1 % (Srivastava, 1999). In the present study, all fishes taken were fat fishes during PRE 09. In all other seasons they were included in the category entitled average fat fish. Lowest protein content was recorded during MON 09 and highest value was recorded in an almost steady state during other seasons in the following order, POM 08> PRE 09 > PRE 1O> POM 09 which couples with high feeding intensity observed by the gorged conditions of stomach.

The percentage ash content in the fishes analyzed is an indication of ample mineral content in fish. The proximate composition of a species helps to assess its nutritional and edible value compared to other species. The chemical compositions of marine organisms are quite close to that of land animals. The principal constituents are water (66 to 84 %), protein (15 to 24 %), lipids (0.1 to 22 %), minerals (0.8 to 2 %) and sugar is in very low quantity (0.3%) at maximum value in fishes (FAO, 1998). The importance of the seasonal variation of proximate composition is complex and it is quite difficult to distinguish the effects of factors in the

biochemical composition of fish (Medford and Mackay, 1978). According to Stansby, (1962), the biochemical constituents are influenced by metabolism, mobility of the fish and geographical area. In the present investigation variations were obtained in the biochemical composition of the fish muscles of different fishes under study, which may be the result of the above processes. The present findings describe the major nutritional composition of different fishes.

The range of values for these constituents in the edible portion of common fish species from Indian coastal waters are: moisture (65-90%), protein (10-22%), fat (1-20%), mineral (0.5- 5%) (source: CIFT library)

Minor quantities of carbohydrates, vitamins, nucleotides, other non-protein nitrogenous compounds etc. are also present and these play vital roles in maintaining the system and thus are essential for growth and development of the organisms.

Fishes are very good sources of protein, providing an important complement to the predominantly carbohydrate-based staple diet of many people in Kerala. The study of the proximate composition of *Oreochromis mossambicus, Mugil cephalus, Channa maruleus, Etroplus suratensis, Etroplus maculeatus, Arius arius, Anabas testudineus* revealed that they are rich in protein and have average to high lipid contents. The present investigation revealed that these fish species are good sources of minerals. It could also be inferred that the mineral elemental levels of each species is a function of the availability and preferential accumulation. Differences in biochemical composition of fish may also occur within the same species depending upon the fishing ground, fishing season, age and sex of the

individual and reproductive status. Spawning cycle and food supplies are the main factors responsible for this variation (Love, 1980).

Statistical Analysis

Correlation

The correlation matrix for the various parameters estimated in water coloumn and phytoplankton are depicted in tables 4.100 to 4.104. In the present study during POM 08, DO showed highly significant negative correlation with Chlorophyceae due to less abundance of this species, while CO_2 exhibited significant negative correlation pointing towards its decrease in concentration caused by photosynthetic uptake. NO_2^- showed highly significant negative correlation with Chlorophyceae while salinity displayed significant positive correlation with Chlorophyceae which inferred the fact that these species flourish in optimum saline habitats. Chlorophyceae exhibited significant negative correlation with transparency and salinity (POM 09). Chlorophyceae showed significant negative correlation with Bacillariophyceae, Myxophyceae and iron (POM 09). The negative correlation with iron implied the uptake of this nutrient metal. Chlorophyceae recorded highly significant negative correlation with ammonia, signaling to the increased uptake of uptake of ammonia from water column for protein synthesis. In the present study, Chlorophyceae showed highly significant negative correlation with Dinophyceae and Myxophyceae and significant negative correlation with Cyanobacteria. Chlorophyceae showed significant positive correlation with silicate (PRE 10).

For Convenience the following abbreviations are used for phytoplankton groups in correlation tables. CP- Chlorophyceae, BP-Bacillariophyceae, DP-Dinophyceae, MP-Myxophyceae, SF-Silicoflagellates, CB-Cyanobacteria, ZP – Zygnematophyceae, DD-Desmidaceae

Bacillariophyceae showed highly significant negative correlation with silicate and exhibited strong positive correlation with alkalinity and salinity during POM 08, implying the effect of salinity on its distribution. Bacillariophyceae showed highly significant positive correlation with Myxophyceae, Zygnematophyceae and highly significant negative correlation with silicoflagellates. Bacillariophyceae showed highly significant positive correlation with NO_3^- (PRE 09). During PRE 10, Bacillariophyceae exhibited highly significant negative correlation with Silicoflagellates, CO_2 and phosphate, inferred the process of uptake of this nutrient and CO_2 during photosynthesis. Since diatoms are highly sensitive to changes in environmental variables such as salinity, tidal currents, flooding frequency, pH and salinity plays an important role in the distribution of these organisms. Bacillariophyceae showed highly significant positive correlation with Zygnematophyceae and exhibited highly significant negative correlation with transparency. The standing crop of phytoplankton showed seasonal variation and spatial variation in the CBW and highest peak was observed during POM 09. Bacillariophyceae (diatoms) were dominant which could well thrive in widely varying hydrographical conditions (Tiwari and Nair, 1998; Rajasegar et al., 2000, Gopinathan et al., 2001, Gowda et al., 2001; Senthilkumar et al., 2002). The dominance of Diatoms (Bacillariophyceae) in the present study was supported by earlier reports of pigment characterization by Aneeshkumar and Sujatha, (2012) which explained the abundance of carotenoid pigment fucoxanthin as an indicator of diatoms.

Alkalinity showed significant negative correlation with Dinophyceae. It was recorded that Dinophyceae exhibited highly significant positive correlation with Zygnematophyceae but significant positive correlation with Cyanobacteria (POM 08). During (PRE 09) Dinophyceae revealed significant positive correlation with phosphate. Dinophyceae exhibited

significant negative correlation with phosphate and significant positive correlation with DO implied the uptake of phosphorous and photosynthetic release of oxygen to water column. Dinophyceae had highly significant positive correlation with Myxophyceae and showed highly significant negative correlation with Zygnematophyceae (MON 09). Dinophyceae exhibited significant positive correlation with salinity and alkalinity and highly significant positive correlation with pH and ammonia and significant negative correlation with CO_2 (POM 09). Dinophyceae exhibited highly significant positive correlation with Myxophyceae (PRE 10).

During PRE 09, Myxophyceae displayed highly significant positive correlation with NO_3^- pointing towards the uptake of this nutrient from water column. It exhibited significant negative correlation with iron and Zygnematophyceae and significant positive correlation with DO (MON 09) pointing towards uptake of iron and release of oxygen during photosynthetic activity. Myxophyceae showed significant negative correlation with Silicoflagellates and Cyanobacteria and significant positive correlation with Desmidaceae. Myxophyceae showed significant positive correlation with NO_2 and salinity (POM 09). During (PRE 10) Myxophyceae showed significant positive correlation with salinity, alkalinity, transparency and iron.

Silicoflagellate significant positive correlation with phosphate and significant negative correlation with NO_3 during (PRE 09) pointing towards the uptake of this nutrient. Silicoflagellates exhibited significant positive correlation with Zygnematophyceae and significant negative correlation with Desmidaceae. Silicoflagellates recorded significant negative correlation with iron owing to the uptake of this nutrient. Silicoflagellates recorded significant positive correlation with DO, transparency and

recorded significant negative correlation with phosphate and salinity (POM 09). These relationships implied the uptake of phosphorous from water column, higher solar insolation and the combined effect of both favours photosynthesis and subsequent release of surplus of oxygen. In the present study, highly significant negative correlation was observed between Silicoflagellates and pH (PRE 10).

Dissolved oxygen exhibited highly significant positive correlation with cyanobacteria revealed the fact that enhanced photosynthetic activity increase dissolved oxygen in the water column. Correlation analysis revealed that alkalinity and salinity had significant negative correlation with Cyanobacteria while, transparency exhibited significant positive correlation (POM 08). In the present study Cyanobacteria exhibited significant negative correlation with NO_2^-, alkalinity, salinity and pH. In the present study it was observed that Cyanobacteria showed significant positive correlation with temperature and DO and highly significant positive correlation with NO_3^- (PRE 10). Cyanobacteria displayed significant negative correlation with ammonia during MON 09, which might be due to preferential uptake of this nutrient for protein synthesis.

Zygnematophyceae recorded highly significant positive correlation with NO_2^- and significant positive correlation with temperature (PRE 09). During PRE 10 Zygnematophyceae recorded significant negative correlation with NO_3 inferred to the uptake of nitrate.

Desmidaceae also showed significant negative correlation with NO_3^- (POM 09) pointing towards the uptake from water column. Chl a showed highly significant positive correlation were found with phosphate and ammonia implying the uptake of these nutrients by plankton (PRE 09).

The highly significant negative correlation existing among different groups of phytoplankton pointed out the presence of a particular group inhibit the existence and growth of another set of phytoplankton due to inter/intra specific competition or predation prevailing in the ecological niche.

Community structure

Community composition and community diversity profiles help to assess the seasonal and spatial variation in the occurrence phytoplankton in the study area. Biotic diversity index is used as an indicator of environmental stress (Sheeba et al., 2004). Generally high level of environmental stress will tend to lower biotic diversity. Different diversity indices help to reach different conclusions (Sheeba et al., 2004; Nisha, 2008). Among the various diversity indices Shannon Weiner index was satisfactory with regard to changes in index value with the variation in pollution intensity (Patil and Taille, 1979).

The results of PRIMER analysis are furnished in tables 4.105 to 4.109. During POM 08 maximum species richness was in S2 (6.89) and minimum at S12 (6.01). The species richness varied from 6.01 to 6.89 (average: 6.28±.0.23). During PRE 09 highest species richness was at S5 (7.64) and minimum at S9 (7.33). The species richness varied from 7.33 to 7.64 (average: 7.45±.0.094). During MON 09, highest species richness was at S4 and minimum at S8. The species richness varied from 6.25 to 6.80 (average: 6.46±0.16). During POM 09, species richness was maximum at S11 and minimum at S15. The value was varied from 7.26 to 7.57 (average: 7.42± 0.09). During PRE 10, species richness was maximum at S6 and minimum at S15. The species richness was minimum at S15 (7.01) which is a polluted industrial belt and maximum at S6 (7.85) (average: 7.52± 0.24).

Species diversity (H' (Log2):

During POM 08, species diversity varied from 5.45 (S6) to 5.71 (S2), (average: 5.57± 0.06). It was found that in PRE 09, value ranged from 5.68 (S6) to 5.81 (S15), (average: 5.74± 0.03). But in MON09, species diversity recorded a minimum of 5.59 (S8) to maximum 5.71 (S4) (average: 5.65± 0.03). During POM 09 value ranged between 5.83 and 6.00 (average: 5.92± 0.04). During PRE 10, species diversity recorded variation between 5.62 (S15) and 5.77 (S8), (average: 5.71± 0.04).

Similarity between stations (Spatial)

Similarity between stations was studied with the help of Bray Curtis similarity index and community coefficient (using only the presence and absence of species). During POM 08, 85% similarity was occurring between S1, S4, S2 and S3; between S5, S6, S7 and S8; and between S15, S14, S13, S12, S11, S10 and S9 using Bray Curtis index. It was recorded that PRE 09 showed 90% similarity occurs between S4, S5, S6, S7 and between S8, S9, S14, S15, S10, S11, S12, S13. 95% similarity occurs between S1, S2 and S3. During MON 09, 90% similarity occurs between stations S4 and S5 and between S6, S7, S8, S9, S10, S11, S12, S13 and S14. 93% similarity occurs between stations S1, S2 between S8 and S14, between S12 and S13; between S10 and S11. Similarity in the species occurrence was highly related to hydrography and sediment characteristics. During monsoon season not much spatial variation was observed compared to other seasons.

During POM 09, 90% similarity occurs between S4, S5, and S6; between S14 and S15; between S12, S11 and S10; between station S7, S8 and S9; between stations S1, S2 and S3. During PRE 10, 90% similarity occurs between 12 stations, except S1, S2 and S15.

Ecologically significant factor groups were presented through cluster analysis by group averaging based on Bray-Curtis similarity index and a comparison was obtained by cluster analysis. Dendrogram constructed for distribution of phytoplankton are depicted in figure 4.6 to 4.10.

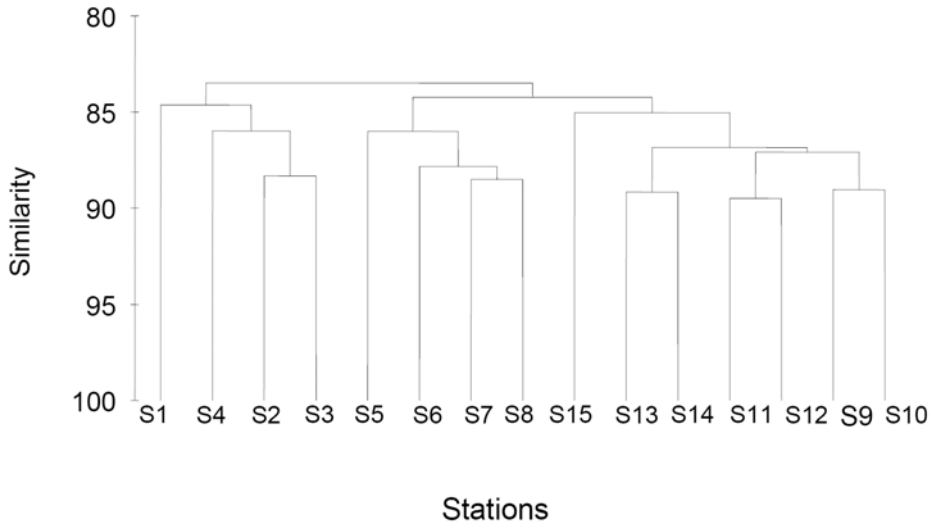

Figure 4.6 Dendrogram showing distribution of phytoplankton (POM 08)

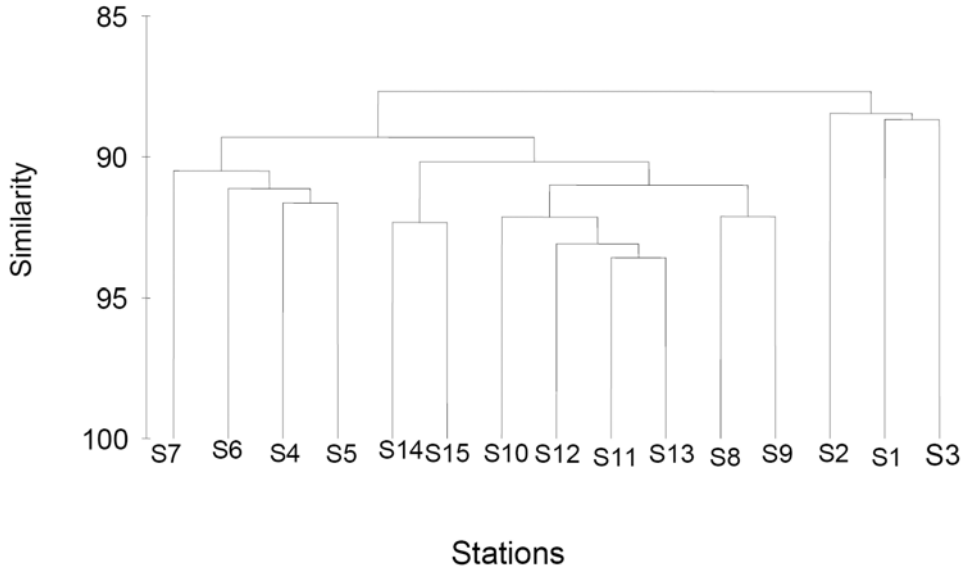

Figure 4.7 Dendrogram showing distribution of phytoplankton (PRE 09)

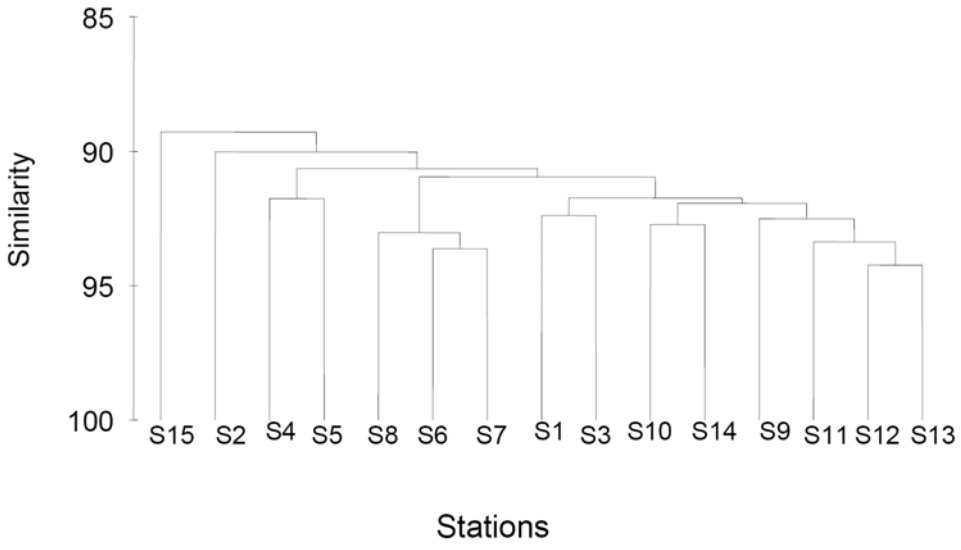

Figure 4.8 Dendrogram showing distribution phytoplankton (MON 09)

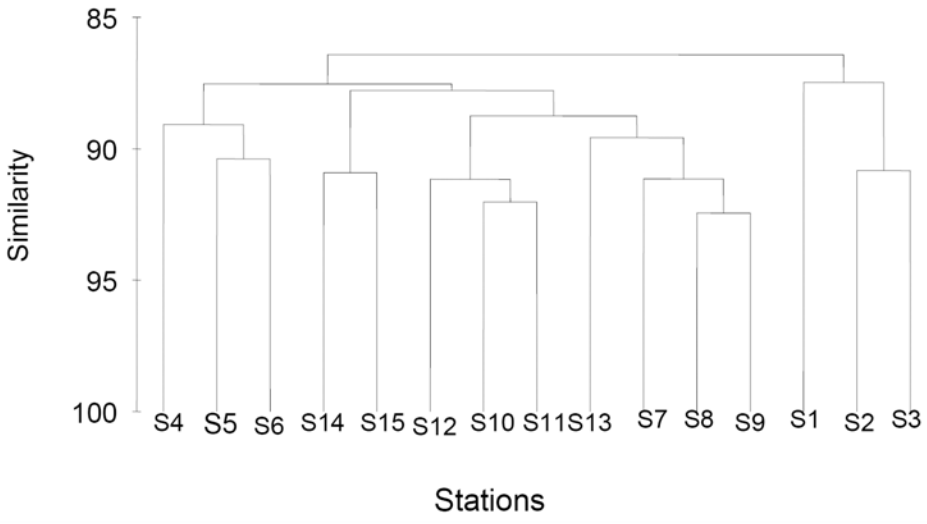

Figure 4.9 Dendrogram showing spatial variation of phytoplankton (POM 09)

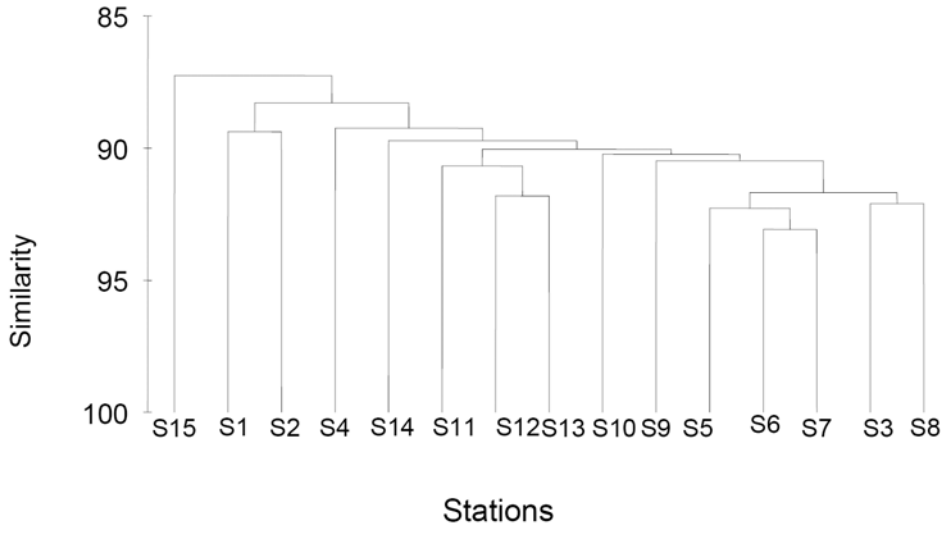

Figure 4.10 Dendrogram showing distribution of phytoplankton (PRE 09)

Species dominance index (Pielou's measure of diversity) ranged between 0.025 (S10) to 0.03 (S1) (average: 0.027±0.001) in the study area during POM 08. During PRE 09, minimum species dominance at S15 and maximum at S6. The value ranged from 0.02 to 0.03 (average: 0.02±0.001). During MON 09, value was ranged between 0.024 (S1) to 0.026 (average: 0.025±0.001). During POM 09, species dominance index of phytoplankton ranged from 0.018 (S13) to 0.022 (S4) (average: 0.02± 0.001). During PRE 10, species dominance index showed uniformity (0.02) (average: 0.02± 0.01). Species dominance index is represented in tables (4.105 to 4.109).

Species evenness in the distribution of phytoplankton species in the study area as measured by Heip's index, a function of Shannon index , showed higher values at S9 (0.92) and lowest value at S6 (0.89) with an average of 0.905± 0.007 during POM 08. It was found that during PRE 09, this value ranged from 0.88 (S5) to 0.90 (S1) and exhibited an average of 0.89±0.006). During MON 09 species evenness exhibited almost same trend in all stations (0.91 and 0.92) (average: 0.91±0.002). During POM 09,

species evenness value showed a common trend in all stations similar to monsoon . During PRE 10 the value varied from 0.88 (S11) to 0.89 (S4), (average: 0.89±0.004). In general higher diversity was followed by lower level of species evenness or equitability in distribution. This leads to the conclusion that existing conditions were favourable for pollution tolerant phytoplankton species. Diversity is important because it is considered as a parameter of a natural or organized community. An inverse relationship between species richness and evenness component of diversity which is mathematically expected can be seen in this study. It can be concluded that the components of diversity viz., richness and evenness are necessary to furnish adequate explanation of species diversity.

According to Kibrige and Perissinotto, (2003) a stress value <0.05 generally represents an excellent similarity. During POM 08 stress was found to be 0.15, low stress value indicates water was less polluted and environmental conditions were favourable for the occurrence of phytoplankton during this season (Nisha, 2008). The stress value during PRE 09 was 0.14 indicated less polluted and favourable environmental conditions. Rainfall was comparatively high during this season.

Figure 4.11 Multi Dimensional Scaling of spatial distribution of phytoplankton (POM 08)

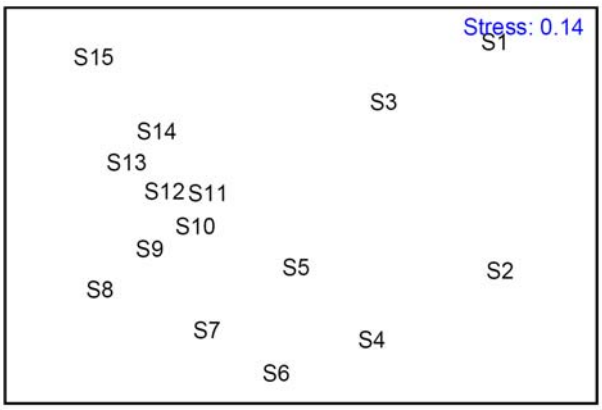

Figure 4.12 Multi Dimensional Scaling of spatial distribution of phytoplankton (PRE 09)

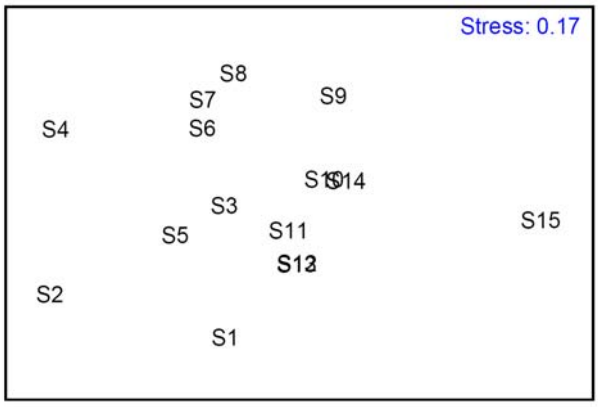

Figure 4.13 Multi Dimensional Scaling of spatial distribution of phytoplankton (MON 09)

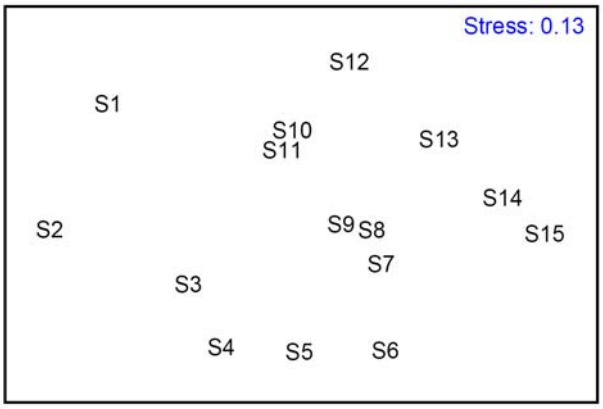

Figure 4.14 Multi Dimensional Scaling of spatial distribution of phytoplankton (POM 09)

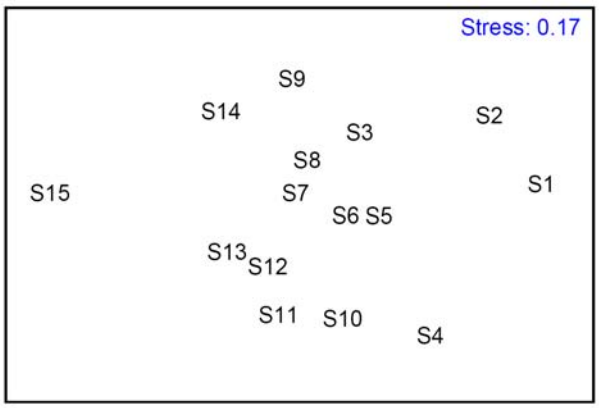

Figure 4.15 Multi Dimensional Scaling of spatial distribution of phytoplankton (PRE 10)

During MON 09, stress value was 0.17 and this indicated the less polluted waters during this season. Compared to other seasons under study, stress value was low (0.13) during POM 09 and this indicated the favourable environmental conditions for the high diversity and richness of phytoplankton during this season. Salinity and other factors were stable during POM 09 the phytoplankton production was more (Nayar and Gowda, 1999; Rajesh et al., 2002) while PRE 10 showed stress value of 0.17 (figures 4.11 to 4.15). In the present study the factors responsible for phytoplankton production vary with the stations in the study area (Joy et al., 1990, Menon et al., 2000). From the study it was observed that generally the nutrients are more enriched at the surface and often these nutrients available in the water column are not fully utilized by the phytoplankton and high concentration were detected in the surface waters. Similar results were also reported by Gopinathan et al (2001).

4.4 Conclusion

The nutrients are more enriched at the surface and often these nutrients available in the water column are not fully utilized by the phytoplankton and high concentrations were detected in the surface waters.

The present study revealed that phytoplankton diversity was more pronounced during premonsoon season, but maximum density was observed during postmonsoon season due to stable hydrographical conditions and less predation. *Skeletonema costatum, Cyclotella meneghiniana* are present which are euryhaline and show abundance. Community composition and community diversity profiles revealed that the seasonal and spatial variation of phytoplankton in the study area. Biotic diversity index is used as an indicator of environmental stress. Generally high level of environmental stress will tend to lower biotic diversity. Different diversity indices help to reach different conclusions. Cyanobacteria displayed significant negative correlation with ammonia during MON 09, which can be attributed to preferential uptake of this nutrient for protein synthesis.

Among the various diversity indices Shanon Weiner index was satisfactory with regard to changes in index value with the variation in pollution intensity. The results showed that production of phytoplankton in the estuary exceeds several times than that of zooplankton. Nitrogen increase in the system is a direct response of human interference. Increase in nitrogen results in excessive growth of phytoplankton. The primary production also presents abundance of phytoplankton which may eventually lead to eutrophication.

It can be concluded that there was insignificant correlation between nutrients and primary production which pointed out the fact that inspite of the higher concentration of available nutrients in the water column, the productivity was restricted by factors like transparency and meteorological factors. The phytoplankton distribution, species composition and dominance are closely associated with the prevailing hydrographic

condition and nutrients. The standing crop of phytoplankton also showed both seasonal and spatial variation in the CBW. Highest peak was observed during POM09. During this peak, Bacillariophyceae (Diatoms) were dominant which could thrive in widely varying hydrographical conditions. Both phytoplankton growth and primary production showed fluctuations according to seasons with respect to annual rain fall. Similarity between stations was studied with the help of Bray Curtis similarity index and community coefficient (using only the presence and absence of species). In general higher diversity was followed by lower level of species evenness or equitability in distribution. It can be concluded that existing environmental conditions were favourable for the growth of pollution tolerant phytoplankton species. Diversity is important because it is considered as a parameter of a natural or organized community. An inverse relationship between species richness and evenness component of diversity which is mathematically expected can be seen in this study. It can be concluded that the components of diversity viz., richness and evenness are necessary to furnish adequate explanation of species diversity. The highly significant negative correlation existing among different groups of phytoplankton explained that the presence of a particular group inhibit the existence and growth of another set of phytoplankton due to inter/intra specific competition or predation prevailing in the ecological niche.

This is an attempt to trace indicators capable of identifying environmental conditions over space and seasons encompassing phytoplankton, zooplankton and fishes, pollution load of CBW ecosystem. The term “shrinking back waters” represent habitat reduction which limits the flushing. Dredging and siltation can result in adverse environment for fishes. Added to these industrial effluents also act as chemical pollutants.

Due to increasing urbanization large volumes of sewage also enters the system. Toxic substances from pesticides and nutrient enrichment from land runoff also contribute adversely. A realistic approach to all these parameters is helpful in assessing the change in the water quality. As shown by Neimi et al., 2004, this study forms a bench mark linking productivity and hydrology in realizing the changes in CBW.

The actual relationship of plankton to fisheries is a subject of intense research and there is the need for further investigation. This is the first step for the detailed classification of phytoplankton, zooplankton and fishes and their distribution in different areas of Cochin back water system. In the present study, seven landing centres adjacent to sampling sites were examined and monthly data were collected for seasonal comparison for fishes captured from the estuary. It was observed that 16 species of major food fishes and 5 crustacean species were abundant and were found to be valued and marketed in the local markets. The decline in the fish production reported from this estuary could also be linked with this observation of a decrease in the meso-zooplankton biomass over the years. The present findings describe the major nutritional composition of different fishes under study. The proximate composition of the commercially important fish species from CBW were studied to assess their nutritional values in order to achieve the knowledge of the risk and benefits associated with the indiscriminate consumption of these species. The fish contains comparatively large amount of protein. These studies warrant that necessary steps should be taken to increase the production and proper management of natural habitat of the species for continued benefits. Data available in literature for proximate composition of individual species will only indicate the range or average and these are not usually taken as

absolute values. Researches on the biochemical (proximate) composition of fish are useful in several ways. Now a day there is an ever-increasing awareness about healthy food and fish is finding more acceptances because of its special nutritional qualities. Proper understanding about the biochemical constituents of fish has become a prime need for the nutritionists and dieticians. The measurement of some proximate profiles such as protein contents, carbohydrates, lipids, moisture contents and ash percentage is often necessary to ensure that they meet the requirements of food.

Chapter 5

SUMMARY

Cochin backwater system exhibits a unique ecological complex having marine, estuarine and fresh water environments at different zones and a large number of organisms inhabit in these environments. Comprehensive studies covering the combined effects of hydrobiology and nutrient dynamics on trophic structure in this ecosystem is scarce. Present investigation was an attempt to evaluate the implications of the hydrobiology and nutrient dynamics on the trophic relationship and community structure in the Cochin backwaters. An integrated approach relating biological as well as physicochemical aspects of this unique backwater system with respect to seasons was employed.

Seasonal samplings of water, sediments primary producers, secondary producers and fish landings were made from fifteen stations in Cochin backwater system during January 2009 (POM 08), April 2009 (PRE 09), August 2009 (MON 09), January 2010 (POM 09) and April 2010 (PRE 10). Water samples (both surface and bottom layers) were collected using Niskin Sampler and surface sediment samples were taken using Van Veen Grab. Water samples for general hydrography and nutrient analysis was subsampled into high density polyethylene bottles, kept on ice bags, transported to laboratory and analysed without delay. Hydrographic parameters such as pH, dissolved oxygen, BOD, carbon dioxide, temperature, salinity, alkalinity, chlorophyll pigments, productivity, depth and transparency were determined by standard procedures. Nutrients like

nitrite- N, nitrate-N, ammonia-N, phosphate, silicate, iron were also estimated in the water samples by spectrophotometric methods. General sedimentary parameters like pH, redox potential, texture, total organic carbon, total nitrogen, and total sulphur were estimated to assess the general geochemical setting of the sedimentary study area. Fractionation of nitrogen and phosphorous in sediments was also carried out to evaluate the enrichment of these nutrients in the estuarine environment. Primary productivity of the study area was investigated by various tools like phytoplankton (qualitative and quantitative), chlorophyll pigments, light and dark DO bottle method. While secondary production was evaluated by zooplankton abundance and tertiary production by fish landings, gut content analysis and proximate composition. Statistical methods were employed to establish the spatiotemporal variation; interrelationships existed among various estimated parameters and trophic interactions (ANOVA, Pearson correlation and PRIMER).

Values of pH in both surface and bottom waters remained slightly alkaline at all the stations. Higher values for pH might be due to the influence of seawater ingression or increased photosynthetic activity. Discharge of floating sediments carried by land runoff as well as dredging operations in Cochin estuary resulted in wide fluctuations in transparency of water column. Higher concentration of dissolved oxygen recorded during monsoon could be due to the cumulative effect of high wind velocity joined with heavy rainfall and the resultant freshwater mixing. The combined effects of higher biological production coupled with sinking of organic matter, discharge of untreated effluents, wastes from aquaculture fields and agricultural fields into the backwater system have contributed to the increased BOD levels. In the present investigation, no vertical

stratification for salinity was observed and fresh water conditions were prevalent during the monsoon and the estimated higher values during post monsoon season could be due to increased rate of evaporation and sea water ingression. Among nutrients, ammonia displayed a non-uniform distribution throughout the entire study period which indicated an exogenic input in the estuary. The increased nitrate level was due to fresh water inflow, organic decomposition and terrestrial run-off during the monsoon season. The lower contents of nitrite during the premonsoon season were due to less freshwater input, higher salinity, higher pH and also uptake by phytoplankton. The higher phosphate content in the water column could be attributed to regeneration and release of total phosphorus from sediment into the water column by turbulent mixing. Silicate exhibited significant negative correlation with salinity, suggesting its input through land runoff.

Texture analysis provided an insight into the grain size of the sediments in the study area. Higher concentration for organic carbon reported at some stations could be attributed to the settling of the terrigenous organic matter derived from land runoff. During monsoon value observed could be attributed to the dilution effects associated with high river discharge. The average TOC/ TS values indicated the periodic anoxia nature of the system where, the sediments undergo sulphate reduction below an oxygenated water column. Fractionation of nitrogen and phosphorous in sediments were carried out to evaluate their various forms and enrichment character. The lower values for C/P and N/P ratio indicated enrichment of phosphorous in sediments of estuarine system. Phosphorus fractions were analyzed to quantify the different fractions of phosphorus in the estuarine sediments in order to assess the processes leading to the

fractional distribution of phosphorus, its bioavailablity and influence on trophic status. The contribution of labile phosphorous to total P pool was higher indicating that sedimentary P can act as a source for this nutrient to water column.

Biochemical composition of sedimentary organic matter in the study region showed a dominance of lipids followed by proteins and carbohydrates. Higher concentrations of lipids and proteins in sediments reflected the productive nature of the system. The dominance of lipids and protein over carbohydrates indicated the nutritional status of organic matter in the sediments of the study region. PRT/CHO and LPD/CHO ratios were useful to evaluate the quality and quantity of organic matter in the estuarine sediments. Estimated PRT/ CHO ratios having values <1 indicated the presence of aged or less degradable organic matter (refractory organic matter). Lower values of LPD/CHO ratio might be attributed to the higher concentration of carbohydrates derived from allochthonous sources. The higher chlorophyll content in the sediments of the study area pointed towards the higher primary production, settling of the pigments to sediment and their preservation due to anoxic conditions. Biochemical composition of sediment also revealed the fact that the trophic state of the study area can be included under meso-oligotrophic condition. The average values of C/N indicated a mixed origin of organic matter ie., autochthonous as well as terrestrial input. The higher tannin and lignin content in the estuarine sediments could be attributed to the input of terrestrial higher plant debris associated with land runoff.

The present study revealed the fact that phytoplankton diversity was more pronounced during premonsoon season, but maximum density was observed during postmonsoon season due to stable hydrographical

conditions and less predation. *Skeletonema costatum, Cyclotella meneghiniana* etc are present which are euryhaline. Phytoplanktons are classified as abundant, rare, common, few according to biomass. Community composition and community diversity profiles revealed the seasonal and spatial variation of phytoplankton in the study area. Among the various diversity indices Shannon Weiner index was satisfactory with regard to changes in index value with the variation in pollution intensity. Biotic diversity index revealed higher level of environmental stress which will tend to lower biotic diversity.

The results of the present study revealed that production of phytoplankton in the estuary exceeds several times than zooplankton. Increase in nitrogen and phosphorous in the system is a direct response of human interference. The present investigation recorded higher phytoplankton production which may lead to eutrophication. The insignificant correlation between nutrients and primary production pointed out the fact that inspite of the higher concentration of available nutrients in the water column; the productivity was restricted by factors like transparency and meteorological parameters. The phytoplankton distributions, species composition and dominance are closely associated with the prevailing hydrographic condition and nutrients. The standing crop of phytoplankton showed seasonal variation and spatial variation in CBW. Highest peak was observed during POM 09. During this peak Bacillariophyceae (diatoms) were dominant which could well thrive in widely varying hydrographical conditions both phytoplankton growth and primary production and showed fluctuations according to seasons. Similarity between stations was studied with the help of Bray Curtis similarity index and community coefficient (using only the presence and

absence of species). In general, higher diversity was followed by lower level of species evenness or equitability in distribution. The results could be included that the existing conditions were favourable for pollution tolerant phytoplankton species. An inverse relationship between species richness and evenness component of diversity which is mathematically expected can be observed in this study. It can be concluded that the components of diversity viz., richness and evenness are necessary to furnish adequate explanation of species diversity. The highly significant negative correlation existing among different groups of phytoplankton explained the presence of a particular group inhibiting the existence and growth of another set of phytoplankton due to inter/intra specific competition or predation prevailing in the ecological niche.

In the present investigation, copepods were present throughout year in the plankton samples and formed the dominant component of the crustacean holoplankton. Copepods like *Acartia centura*, *Acartia spinicauda*, *Acartia bowmani*, *Acartia southwelli*, *Acartia pacifica* and *Acartia plumosa* were present during all seasons except monsoon. The zooplankton distribution in the back waters suggests that the salinity is the major limiting factor controlling their abundance. All groups showed remarkable seasonal distribution with respect to changes in salinity and other environmental factors. It was found that population density of zooplankton in the estuary was no way limited by primary production, which throughout the year far exceeds the consumption by zooplankton.

Fish stock assessment was made from seven fish landing centres in the study area. Monthly data were collected for seasonal comparison for fishes captured from the estuary. It was observed that 16 species of major food fishes and 5 crustacean species were identified which were found to

be valued and marketed in the local markets. The decline in the fish production was observed during the investigation. The proximate composition of the commercially important fish species from CBW were studied to assess their nutritional values in order to achieve the knowledge of the risk and benefits associated with the indiscriminate consumption of these species. This study would help us for taking necessary steps which should be taken to increase the production and proper management of natural habitat of the species. Differences in biochemical composition of fish may also occur within the same species depending upon the fishing ground, fishing season, age and sex of the individual and reproductive status. The estimation of proximate composition was carried out in the present investigation which revealed seasonal variation. The main causes are spawning cycle and food supplies and are the main factors responsible for this variation. Proper understanding about the biochemical constituents of fish has become a prime need for the nutritionists and dieticians.

The integrated approach involving hydrobiology, nutrient dynamics and productivity and trophic level interactions will be useful to implement corrective measures to restore the health of Cochin backwater system and implementation of sustainable management practices. The present study would serve as a reference for the future investigations in this ecosystem.
